Rehab O. Abdel Rahman is Associate Professor of Chemical Nuclear Engineering at the Radioactive Waste Management Department, Hot Laboratories and Waste Management Center, Atomic Energy Authority of Egypt. She has a PhD in Nuclear Engineering from Alexandria University, Egypt. She has contributed to the publication of more than thirty peer-reviewed scientific papers, fourteen book chapters and eight books. Dr. Rahman has contributed in teaching and supervising postgraduate research in chemistry, physics, petrochemicals and environmental–chemical engineering. She serves as a verified reviewer for several journals and is managing editor for the *International Journal of Environment and Waste Management* and *International Journal of Engineering Education*. Dr Rahman is an honored scientist of Academy of Scientific Research and Technology and a Publons top reviewer (2016–2019).

The application of isotopes in exploring different ecological, biological, chemical and geological systems is receiving considerable attention. These applications aim to understand the dynamics of different environmental compartments including hydrosphere, atmosphere, and lithosphere, explore natural resources, plan for water management, assess and predict climatic changes and trace the migration of pollutants. This book provides a wide scope of topics related to the principles and recent advances in the applications of isotopes in the earth sciences. It describes the theoretical background on radioactivity phenomenon, including the identification of the radiological characteristics of natural and anthropogenic isotopes and isotope fractionation processes. It also examines the applications of these isotopes to understand the natural processes in different compartments of the Earth.

The book consists of two sections that cover important research efforts in applying isotopic techniques in earth science. The first section presents some isotopic applications in the lithosphere. Dr. Li et al. present an overview of the formation, sources, transport and fractionation of different natural and anthropogenic isotopes. Their applications in understanding soil redistribution and sedimentation mechanisms are illustrated by demonstrating the feasibility of applying isotopes and icescape modeling. Dr. Manjate uses metamorphic zircon morphology, Th/U ratio, and 207Pb/206Pb to date the tectono-metamorphic event in Macossa-Chimoio Nappe Mozambique.

The second section illustrates some isotopic applications in the hydrosphere. Dr. Li et al. present the applications of stable sulfur, strontium, boron, oxygen and deuterium to study brine origin. Their application is directed to study Qaidam Basin, NE Tibetan Plateau. Dr. Khayat et al. apply stable isotopes to identify recharge–discharge zones and study groundwater flow regimes and the connection between sub-basins. Their applications are directed to support planning for water management by combining isotope analysis with the geological and hydrogeological setting in the West Bank, Palestine. Finally, Dr. Leclerc applies the concept of oxygen isotopic fractionation to investigate the effect of temperature and light intensity on biological and isotopic changes.

I would like to thank all the authors for their efforts that led to the production of this distinguished scientific contribution. A special acknowledgment is directed to Author Service Manager Mr. Mateo Pulko for his coordination efforts.

Chapter 1
Isoscape Analysis for Elucidating Relationships between Soil Redistribution and Soil Carbon Dynamics
Xia Li, Gregory McCarty and Sangchul Lee

Abstract
Isotopic tracers are useful for assessing linkages between soil movement and soil carbon dynamics in landscapes. Analyses of isotopes and comparison of isoscape (isotopic landscape) with observational data have been employed to investigate spatial distributions of isotopes, to test efficiencies of isotopic models, and to examine soil redistribution patterns and C dynamics. This chapter reviewed the application of natural (7Be, 210Pb) and anthropogenic fallout radionuclides (137Cs, 239,240Pu), and C isotopes (12,13,14C) in understanding mechanisms of soil redistribution and sedimentation. The chapter was organized to cover the formation, sources, and transport of these isotopes; how they are distributed and related to soil redistribution on C dynamics; and importance of their distribution (isoscapes) on investigating soil properties. We also provided a case study to demonstrate the feasibility of applying isotopes and isoscape modeling for understanding soil property variability in response to anthropogenic disturbance in a low-relief cropland field. Results demonstrated advantages of using 137Cs and C isotopic signature (\(\delta^{13}C\)) to trace soil movements and C dynamics. Topography-based 137Cs and C isoscape models were developed using light detection and ranging data (LiDAR) derived topographic metrics. The models successfully simulated the spatial patterns of 137Cs inventory and \(\delta^{13}C\) over an agricultural landscape and can benefit soil sedimentation and C dynamic studies in areas with limited observations.

Keywords: isotope analysis, isoscape, soil redistribution, soil carbon dynamics, dynamic replacement

1. Introduction
Soil redistribution (i.e., erosion and deposition) exerts a significant impact on the global carbon (C) cycle. Movement of soil particles could either redistribute soil C or change the C mineralization through disruption of soil aggregation, reaggregation of deposited soils, and deep burial of C-enriched sediments at depositional sites [1]. When soil erosion occurs, the surface concentrated and low-density proportions of sediments, such as soil organic carbon (SOC), are preferentially removed by runoff, wind, and/or tillage activities. A greater SOC enrichment ratio in eroded sediment is usually observed compared to its origin [2]. The eroded

Isoscape Analysis for Elucidating Relationships between Soil Redistribution and Soil Carbon Dynamics

Xia Li, Gregory McCarty and Sangchul Lee

Abstract

Isotopic tracers are useful for assessing linkages between soil movement and soil carbon dynamics in landscapes. Analyses of isotopes and comparison of isoscape (isotopic landscape) with observational data have been employed to investigate spatial distributions of isotopes, to test efficiencies of isotopic models, and to examine soil redistribution patterns and C dynamics. This chapter reviewed the application of natural (\(^{7}\)Be, \(^{210}\)Pb) and anthropogenic fallout radionuclides (\(^{137}\)Cs, \(^{239,240}\)Pu), and C isotopes (\(^{12,13,14}\)C) in understanding mechanisms of soil redistribution and sedimentation. The chapter was organized to cover the formation, sources, and transport of these isotopes; how they are distributed and related to soil redistribution on C dynamics; and importance of their distribution (isoscapes) on investigating soil properties. We also provided a case study to demonstrate the feasibility of applying isotopes and isoscape modeling for understanding soil property variability in response to anthropogenic disturbance in a low-relief cropland field. Results demonstrated advantages of using \(^{137}\)Cs and C isotopic signature (\(\delta^{13}\)C) to trace soil movements and C dynamics. Topography-based \(^{137}\)Cs and C isoscape models were developed using light detection and ranging data (LiDAR) derived topographic metrics. The models successfully simulated the spatial patterns of \(^{137}\)Cs inventory and \(\delta^{13}\)C over an agricultural landscape and can benefit soil sedimentation and C dynamic studies in areas with limited observations.

Keywords: isotope analysis, isoscape, soil redistribution, soil carbon dynamics, dynamic replacement

1. Introduction

Soil redistribution (i.e., erosion and deposition) exerts a significant impact on the global carbon (C) cycle. Movement of soil particles could either redistribute soil C or change the C mineralization through disruption of soil aggregation, reaggregation of deposited soils, and deep burial of C-enriched sediments at depositional sites [1]. When soil erosion occurs, the surface concentrated and low-density proportions of sediments, such as soil organic carbon (SOC), are preferentially removed by runoff, wind, and/or tillage activities. A greater SOC enrichment ratio in eroded sediment is usually observed compared to its origin [2]. The eroded
Isotopes Applications in Earth Sciences

sediment is either redistributed over a landscape or deposited at depressional sites. Therefore, investigation of soil redistribution and underlying mechanisms are needed for better understandings of the fate of soil C within the landscape.

Various methods have been developed to quantify soil redistribution. Before the 1990s, researchers mainly focused on understanding soil erosion by discerning changes in soil texture and chemical properties [3]. However, accuracy of this method was low, mainly because impacts of erosion on soil properties are complicated and vary with soil characteristics, soil depth, and local land use practices. Other studies adopted erosion prediction models, such as the USLE, WaTEM, and WEPP, to assess soil redistribution processes [4, 5]. Although these models reasonably estimated long-term mean erosion rates over large-scale, the estimates from the modeling are often mean redistribution rates at sites, model estimates from individual erosion events are too coarse to be linked to each soil samples to explain changes in soil properties [6].

The emergence of isotopic analysis allows researchers to accurately trace soil movement at locations, offering a potential way to quantify the impacts of soil erosion and deposition on soil properties. The isotopic tracer selection follows two criteria: (1) isotopes should be able to quickly and strongly absorbed by the soil; and (2) the variability in absorption to various textures or size is either minor or can be calculated [7]. A tracer can be uniformly distributed at first and then move with the soil movements, presenting mass variations between eroded and depositional sites.

This chapter examines the application of six widely used tracers, including anthropogenic fallout radionuclides/Cesium-137 (137Cs), plutonium isotopes (239,240Pu), natural fallout radionuclides Beryllium-7 (7Be), Lead-210 (210Pb), and C isotopes (12,13,14C), in soil redistribution and C distribution studies. Objectives of this chapter are to (1) review impacts of soil redistribution on soil C dynamics; (2) summarize critical processes regulating the selected soil isotopes; (3) introduce the concept of isoscape and its applications in soil biogeochemical studies; and (4) provide discussion of isotopic and isoscape analyses for understanding of soil redistribution and carbon dynamics through a case study.

2. Soil redistribution impacts on soil C dynamics

The global soil inventory represents an important C pool (Figure 1) with a total of 1950 Gt C, accounting for 2.3 times the size of the atmospheric C pool (860 Gt C) and 3.5 times of the biotic C pool (550 Gt C) [8]. About 1750 Gt C of total soil C concentrates on land surface, where soil erosion and deposition processes are intense. The light and fine soil particles with high SOC content are preferentially removed by the erosion process and redistributed over a landscape or deposited at depressional sites. It was estimated that 75 Gt year⁻¹ of soil is removed by water and wind erosion [1], which contribute to 0.8–2.2 Gt year⁻¹ emission of C from land surface, and 2.5–3.9 Gt year⁻¹ of replaced C in soil [8].

Although researchers have increasingly recognized the importance of soil erosion and C dynamics on ecosystems, mechanisms of soil redistribution controls on soil C remains poorly understood. Some studies suggested negative effects of soil erosion on terrestrial C sequestration [9–11]. They provide an argument that excessive soil erosion can lead to losses of soil fertility, decreasing the plant and crop productivity [9]. Notably, the recently accelerated soil erosion due to agricultural activities has caused 2 billion ha of land being irreversibly degraded [1]. Plowing activity increases the possibility of soil organic matter within the plow layer to be exposed to anthropogenic and climatic perturbations, and thus accelerates SOC mineralization [11]. Furthermore, soil C mineralization in displaced soils can also
be stimulated as a result of the breakdown of soil aggregates by raindrop and runoff shearing forces that expose previously protected organic matters to oxidation [12]. It was estimated that more than 20% C emission was caused by mineralization of the displaced C [13].

On the contrary, arguments for positive impacts of soil redistribution on C storage support that redistribution of soil could increase C sequestration in terrestrial ecosystems [14–17]. SOC losses at the eroded sites could be dynamically replaced by litter input from plant regrowth and return of above- and below-ground biomass to soil and replenish the depleted SOC pool at eroded sites [18, 19]. The eroded SOC is subsequently buried and re-aggregated at depressional sites, protecting SOC from mineralization and thus increasing C sequestration [14, 20, 21]. Stallard [19] used a large set of scenarios estimated that the human-induced C burial is in the range of 0.6–1.5 Gt C year$^{-1}$ by terrestrial sedimentation.

3. Using isotopes in studies of soils and sediments

3.1 Anthropogenic fallout radionuclides

$^{137}$Cs is the most widely used isotope in geomorphic studies of water, wind and tillage erosion. As an anthropogenic radionuclide with a half-life of 30.2 years, $^{137}$Cs was released globally into the environment due to radioactive fallout from nuclear weapon testing in the 1950s and 1960s and reached to land surface through wet and dry deposition (Figure 2). Additional $^{137}$Cs fallout occurred because of the 1986 Chernobyl accident in the north of the Ukrainian SSR and the 2011 Fukushima accident in Japan. The overall amount of $^{137}$Cs released from Fukushima was less than 15% of the amount from the Chernobyl accident [22]. The Fukushima accident added high amounts of $^{137}$Cs to soils near the accident site, but the large-scale plume of radioactive fallout extended mainly over the Pacific Ocean which reduced the extent of terrestrial labeling. In contrast, Chernobyl is in the center of the European continent. The released fallout radionuclides significantly increased the $^{137}$Cs amount in many European countries [22]. $^{137}$Cs is chemically active and is rapidly and strongly absorbed by fine soil particles when it contacts with the soil. Vertical migration is slow and the majority of $^{137}$Cs is retained in the upper 20 cm of the soil surface across the globe [23–25]. Once the soil is labeled by $^{137}$Cs, chemical and
biological removal of $^{137}\text{Cs}$ is low. The $^{137}\text{Cs}$ concentration changes mainly result from physical processes in the top-layer soils, such as soil transport and deposition. Therefore, these characteristics make $^{137}\text{Cs}$ a useful tracer for quantifying of soil redistribution rates.

Previous investigations have reported strong and statistically significant correlations between $^{137}\text{Cs}$ and soil C [10, 26, 27]. However, because $^{137}\text{Cs}$ inventory is usually non-linearly correlated with soil redistribution, the correlations between $^{137}\text{Cs}$ inventory and soil C content are usually weaker than the correlations between soil redistribution process and SOC [6]. Consequently, instead of directly quantify SOC based on $^{137}\text{Cs}$, most recent studies first converted $^{137}\text{Cs}$ measurements to soil redistribution rates, and then used the estimates to link to soil C content. Specifically, the application of $^{137}\text{Cs}$ measurements in soil redistribution and C dynamics mainly includes to (1) calculate soil redistribution at a point and link to soil properties of a soil sample from the same point [6, 28, 29]; (2) provide mean annual rate of soil redistribution over 60 years and reflect the erosion history of a site [10, 29]; and (3) present spatial patterns of soil erosion and deposition over the landscape [27, 30]. Because of the short half-life, $^{137}\text{Cs}$ concentration may drop below the detection limits quickly and limit use of this tracer in SOC investigations. Researchers are finding alternative tracers with longer half-lives for soil erosion investigation. Anthropogenic radionuclides of two major plutonium isotopes ($^{239}\text{Pu}$: half-life = 24,110 years and $^{240}\text{Pu}$: half-life = 6561 years) are considered as potential alternatives for this purpose. Like $^{137}\text{Cs}$, the Pu isotopes in soils are also mainly from nuclear weapon testing between the 1950s and 1960s following the 1986 Chernobyl accident. However, the isotopic composition of Chernobyl Pu ($^{240}\text{Pu}/^{239}\text{Pu}$ atom ratio: 0.37–0.41) presents higher ratios compared to Pu from nuclear testing ($^{240}\text{Pu}/^{239}\text{Pu}$ atom ratio = 0.180 ± 0.014), which can be used to distinguish Pu isotopes from the two sources [31]. Some researchers have argued that in soils with high organic matter, Pu might be preferentially absorbed by organic fractions with high molecular weight and potentially lead to a deep vertical migration [32, 33].

Considering the long half-life of Pu isotopes, increasing studies have explored the feasibility of using Pu isotopes in investigations of soils and sediments [34–36]. Schimmack et al. [37] found that the Chernobyl Pu could be a better tracer for soil redistribution detections in Bavaria, Germany, since spatial patterns of Pu agreed
better with soil mapping than that of \(^{137}\text{Cs}\). Similar conclusions were reached in several other studies, reporting more homogenous distributions of \(^{239,240}\text{Pu}\) than \(^{137}\text{Cs}\) in parts of Europe that were influenced by the Chernobyl accident \([31, 38]\). Thus, the isotopic composition variations may lead Pu isotopes to be a better choice than \(^{137}\text{Cs}\) for tracing soil erosion. However, the feasibility of applying \(^{239,240}\text{Pu}\) to soil erosion and soil C investigations still needs further testing because of its vertical migration and lateral transport by water, which may influence the quantification of soil redistribution \([39, 40]\).

### 3.2 Natural radionuclides

\(^{7}\text{Be}\) is a natural radionuclide produced primarily through cosmic-ray spallation of oxygen and nitrogen nuclei in the stratosphere and troposphere. Unlike the anthropogenic radionuclides of \(^{137}\text{Cs}\) and \(^{239,240}\text{Pu}\), wet and dry deposition of \(^{7}\text{Be}\) to the soil surface is continuous because of its natural origin \([41]\). The concentration of \(^{7}\text{Be}\) in the soil decreases with increases in particle size \([42]\). Vertical migration was low for this isotope due to its relatively short half-life (half-life = 53.3 days). Wallbrink and Murray \([42]\) found that most of soil \(^{7}\text{Be}\) was accumulated in the top 20 mm regardless of soil types and surface cover conditions at two Australian sites.

Because of its short half-life, \(^{7}\text{Be}\) has the potential to trace short-term soil redistribution. A number of studies have used this isotope to examine short-term soil erosion after heavy rain events, providing a basis for understanding sediment transported by dispersed overland flow \([41–44]\). Considering the lower vertical transport of \(^{7}\text{Be}\) relative to \(^{137}\text{Cs}\) and excess \(^{210}\text{Pb}\) \((^{210}\text{Pb}_{\text{ex}})\), this isotope has been applied to discriminate vertical and horizontal erosion by combining with the other two isotopes \([45, 46]\). Ryken et al. \([47]\) suggested correction factors related to particle size and variations in relaxation mass depth should be used to get precise estimates of \(^{7}\text{Be}\)-derived soil redistribution rates. Li et al. \([48]\) successfully applied \(^{7}\text{Be}\) to quantify SOC sequestration changes caused by land-use and management activity.

Another natural isotope, Lead-210 \((^{210}\text{Pb})\) produced through the decay of gaseous Radon-222 \((^{222}\text{Rn})\) generated from the decay of Radium-226 \((^{226}\text{Ra})\) in the Uranium-238 \((^{238}\text{U})\) decay series. \(^{226}\text{Ra}\) exists in soils and rocks. Most of \(^{226}\text{Ra}\) decay to \(^{210}\text{Pb}\) in situ, which is termed supported \(^{210}\text{Pb}\). Due to diffusion, a small portion of \(^{226}\text{Ra}\)-derived \(^{222}\text{Rn}\) enters to the atmosphere and subsequently introduces \(^{210}\text{Pb}\) to the atmosphere. This kind of \(^{210}\text{Pb}\) falls to land surface through wet and dry deposition and is termed unsupported or excess \(^{210}\text{Pb}\) \((^{210}\text{Pb}_{\text{ex}})\). The \(^{210}\text{Pb}_{\text{ex}}\) is strongly absorbed by fine soil particles and transports with soil movement. \(^{210}\text{Pb}_{\text{ex}}\) fallout is continuous over time, which is like \(^{7}\text{Be}\), but its half-life (half-life = 22.3 years) is longer than \(^{7}\text{Be}\). Therefore, \(^{210}\text{Pb}_{\text{ex}}\) has the potential to penetrate deeper soil layers (to 10 cm) than \(^{7}\text{Be}\) \([7, 23]\).

The use of \(^{210}\text{Pb}_{\text{ex}}\) in soil and sediment studies has increased in recent decades. Due to the continuous fallout, \(^{210}\text{Pb}_{\text{ex}}\) can be used to provide long-term soil redistribution rates. Meanwhile, unlike \(^{137}\text{Cs}\), \(^{210}\text{Pb}_{\text{ex}}\) does not have below-detection-limit problems caused by medium-lived anthropogenic fallout radionuclides. In practice, two or more different fallout radionuclides can be used to understand the soil erosion history. \(^{210}\text{Pb}_{\text{ex}}\) is combined with \(^{137}\text{Cs}\) and/or \(^{7}\text{Be}\) to provide soil redistribution records in the past 100 years. Several studies suggested that \(^{210}\text{Pb}_{\text{ex}}\) and \(^{7}\text{Be}\) can produce similar spatial patterns \([45, 49]\), but differences resulting from different land uses could help sediment source identification \([46, 50]\). Increasing applications of \(^{210}\text{Pb}_{\text{ex}}\) in C dynamic studies have been reported recently \([10, 15, 51, 52]\). Investigations have demonstrated that \(^{210}\text{Pb}_{\text{ex}}\) is preferentially associated with SOC than \(^{137}\text{Cs}\), due to the stronger binding to the organic matter in soils \([53, 54]\).
3.3 C isotopes

The origin of soil C isotopes ($^{12}$C, $^{13}$C, and $^{14}$C) is mainly from plant litter entering the soils. During photosynthesis, plant species absorb atmospheric carbon dioxide (CO$_2$), which consists of about 98.9% of $^{12}$CO$_2$, 1.1% of $^{13}$CO$_2$, and trace amount of $^{14}$CO$_2$ (1 part in trillion). $^{14}$C is a natural radionuclide created primarily by the cosmic-ray spallation of nitrogen in the troposphere and the stratosphere. $^{14}$C is a relatively stable radioactive isotope with a half-life of 5730 years [55]. This C isotope is assimilated during plant photosynthesis and entering soil through litter fall and commonly used for age dating.

Data on the stable C isotopes $^{12}$C and $^{13}$C are usually reported $\delta^{13}$C representing deviation of measured $^{13}$C from the established natural abundance with units of parts per thousand (%). Variations in soil $\delta^{13}$C values are controlled primarily by carbon input from plant litter. Due to isotopic discrimination by their photosynthetic enzymes and the regulation of stomatal diffusion resistance, $\delta^{15}$C values in plants cover a wide range. Plants with C3 photosynthesis have $\delta^{13}$C values in a range of $\sim$22 to $\sim$32%. Plants with C4 photosynthesis are less depleted in $^{13}$C with $\delta^{13}$C values ranging from $\sim$9 to $\sim$17%. After plant residues entering the soil, the $\delta^{13}$C value may change slightly due to isotope fractionation during microbial decomposition.

Soil C isotopes can effectively detect soil redistribution and reflect soil C dynamics over the landscape. Because of the isotopic variability in different plant species, soil $\delta^{13}$C has been successfully applied to distinguish eroded soil sources and to identify soil sources from different land use types [56, 57]. Furthermore, due to the significant difference of C isotopic ($\delta^{13}$C and $^{14}$C) values between surface soils and subsoils, scientists also utilized the isotopes to obtain a better understanding of the origins and age of eroded SOC [2, 57]. Trends of $\delta^{13}$C and $^{14}$C by soil depth can be used to reconstruct history of vegetation succession based on different isotopic compositions [55, 58]. Li et al. [29] used both $\delta^{13}$C and $^{137}$Cs to investigate soil C fate in an agricultural field under an annual crop rotation of soybean (Glycine max [L.] Merr.) and maize (Zea mays L.) which represent C3 and C4 crop types respectively. They found that only C3-derived SOC was highly correlated with soil redistribution rates. The results indicated that SOC from different plant species might have different responses to physical disturbances (i.e., erosion and deposition) and biogeochemical transformations such as SOC mineralization.

4. Use of isoscapes in studies of soils and sediments

The spatial and temporal features of isotopes in various environmental materials can be predicted using both landscape and biogeochemical models [59]. The term of isoscape was introduced in the 2000s to describe spatial patterns of isotopes produced by various quantitative models using several environmental variables as predictors [60, 61]. Now isoscape analyses are widely used as a tool to understand the biogeochemistry of landscapes under study. Applications of isoscapes on soils and sediments can be categorized into three groups:

1. Isotopes can be used as the baseline in modeling studies. With the help of a robust model, regional isotopes can be estimated from gridded environmental datasets. Isoscapes provide a powerful tool for probing the efficiencies of these prediction models [62];
2. Comparison of isotopic spatial patterns with observed soil organic C and nitrogen (N) is useful for investigating the impacts of soil redistribution on soil properties. Isoscapes can effectively reflect soil redistribution patterns across space, which can be used to better explain spatial variability of soil properties [29, 63, 64];

3. Soil isoscapes are also used in investigations of plant and animal isoscapes. For example, because the primary input of $^{12}$C and $^{13}$C to soil are from plant litter, maps of soil $^{13}$C isoscape could provide information related to the biogeography of C3 and C4 plants and their relative contributions to the atmospheric C sequestration [65].

5. Application of isotopic analysis in an agricultural field

5.1 Study area introduction

A case study is presented to demonstrate the application of isotopic analysis and isoscape modeling in investigation of soil redistribution and C dynamics in cropland. The study was conducted in an agricultural field in Walnut Creek Watershed (WCW), Iowa. The WCW is in a humid continental climatic zone with relatively flat terrain (Figure 3a). Representative soils are a poor-drained Nicollet (mesic Aquic Hapludolls) in the lowlands and well-drained Clarion (mesic Typic Hapludolls) in the uplands. The dominant land use type in the WCW is agriculture. More than 86% of the watershed is farmlands. Primary tillage practices in the watershed are chisel plowing in autumn and disking in spring. The directions of tillage depend on the farm management and field configuration. Most of the area followed the north-south or east-west tillage directions.

Figure 3.
Elevation variability of (a) Walnut Creek Watershed (WCW) and (b) the cropland field, and (c) relief variability of the cropland field.
The studied cropland field is about 15 ha (Figure 3b). The maximum elevation change within a radius of 90 m is 4.5 m (Figure 3c). A C4–C3 crops rotation (i.e., maize-soybean) has been adopted in this area since 1957, which make this field an appropriate testbed for a detailed C isotope study assessing impacts of soil redistribution.

5.2 Methods

5.2.1 Sampling and laboratory analyses

Isotopes of $^{137}$Cs, $^{12}$C, and $^{13}$C were measured in soil samples. A total of 119 locations were collected at grid nodes in a 25 × 25 m grid. A 9-sample and an 11-sample transects were set at an interval of 12.5 m within the grid (Figure 2b and c). We also selected four reference sites for estimating the baseline $^{137}$Cs inventory. Three samples were collected from the top 30 cm of soil within a 1 × 1 m quadrate using a 3.2 cm diameter push probe at each location. All soil samples were oven dried and weighed for soil bulk density calculation.

SOC content was estimated as the difference between total C that was measured by a LECO CNS 2000 elemental analyzer and calcium C estimated using soil samples ashed in a furnace at 420°C. SOC content (%) was then converted to SOC density (kg m$^{-2}$) using soil bulk density.

The $^{13}$C/$^{12}$C isotope ratio was measured using an isotope-ratio mass spectrometer (Europa Scientific Ltd., Crewe, England). The ratio was then combined with the laboratory reference that was calibrated against the international PeeDee Belemnite (PDB) to estimated $\delta^{13}$C related to PDB.

This study estimated the relative contribution of C3 and C4 crops using the following equations:

$$F_{C4} = \frac{\delta^{13}C - \delta^{13}C_{C3}}{\delta^{13}C_{C4} - \delta^{13}C_{C3}}$$  \hspace{1cm} (1)

$$F_{C3} = 1 - F_{C4}$$  \hspace{1cm} (2)

where $F_{C4}$ and $F_{C3}$ are contribution fraction of C4- and C3- derived SOC, respectively. $\delta^{13}C_{C3}$ and $\delta^{13}C_{C4}$ are the isotopic signatures for C3 and C4 crops. According to the literature review, the average $\delta^{13}C_{C3}$ and $\delta^{13}C_{C4}$ values for soybean and maize are $-27$ and $-12\%$. Therefore, we used these two values to obtain the likelihood C3- and C4-derived SOC in this field.

To measure $^{137}$Cs, gamma-ray analysis was performed using a Canberra Genie-2000 Spectroscopy System. Original unit of $^{137}$Cs concentration was becquerels per gram (Bq g$^{-1}$), and this unit was subsequently converted to becquerels per square meter (Bq m$^{-2}$) using soil bulk density. The baseline $^{137}$Cs inventory estimated from reference sites and the $^{137}$Cs inventory of sampling sites were used to calculate $^{137}$Cs-derived soil redistribution rates using the Mass Balance model I developed by Walling et al. [66]. In this study, the baseline $^{137}$Cs inventory was 2657 Bq m$^{-2}$. Sites with higher $^{137}$Cs inventories than the baseline were considered as depositional sites; while sites with lower $^{137}$Cs inventories were referred as eroded sites.

Additional sampling and laboratory analyses details are given in Li et al. [29].

5.2.2 Historic orthophoto interpretation

Historic orthophotos in the 1950s and 2002 were obtained from the Iowa geographic map server (http://ortho.gis.iastate.edu/) to visualize soil movement. The
surface soil layer was referred as mollic epipedon formed under grass vegetation that dominated this area prior to the 1850s. The mollic epipedon has a characteristic black color and contains a high amount of soil organic matter. Therefore, the black mollic epipedon can be visually identified in the historic orthophoto, serving as an indicator for soil erosion and deposition investigation after the 1850s. In this study, greyness values were derived from the orthophotos to quantify the intensity of black carbon signal related to the mollic epipedon. The values were compared to $^{137}$Cs-derived soil redistribution rates to assess the appropriateness of using $^{137}$Cs to trace soil movement in this low-relief cropland.

5.2.3 Terrain analyses

Topographic metrics used to describe features of the landscape were generated from the light detection and ranging (LiDAR)—derived 3 m digital elevation model (DEM). Fourteen topographic metrics were developed, including slope, profile curvature ($P_{Cur}$), plan curvature ($P_{Cur}$), general curvature ($G_{Cur}$), flow accumulation (FA), topographic relief [topographic relief principal components (TRPCs) and topographic relief factors (TRFAs)], positive topographic openness (PTO), downslope index (DI), flow path length (FPL), catchment area (CA), topographic wetness index (TWI), stream power index (SPI), upslope slope (UpSl), and flow length factor (LS) (Table 1). Before calculating topographic metrics, the DEM was filtered twice through a low-pass 3-by-3 filter. Maps of slope, $P_{Cur}$, $P_{Cur}$, $G_{Cur}$, PTO, DI, FPL, CA, TWI, SPI, UpSl, and LS were developed by the System for Automated Geoscientific Analyses (SAGA) v. 2.2.5 [67]. FA map was generated with ArcGIS.

For TRPCs, a series of topographic relief maps with different spatial scales were generated. The topographic relief shows the elevation differences between the filtered DEM and a maximum elevation map showing a continuous surface of maximum elevation within a specific area/radius. Seven relief images were generated from seven maximum elevation maps using radiiuses of 7.5, 15, 30, 45, 60, 75, and 90 m. Principal component analysis (PCA) was conducted to convert the seven reliefs to seven independent components, and the first two topographic relief principal components (TRPC1 and TRPC2) were selected for further analysis. Similarly, varimax rotated Factor Analysis (FAn) was used and the first two TRFA1 and TRFA2 were selected. The detailed topographic processing can be found in Li et al. [68].

5.2.4 Statistical analysis and model calibration

Duncan’s multiple range tests ($p \leq 0.05$) were applied to test the mean differences of soil texture, soil SOC density, $\delta^{13}$C, $^{137}$Cs inventory, $^{137}$Cs-derived soil redistribution rates, and likelihood C3- and C4-derived SOC density between eroded and depositional sites. Topographic metrics of the 128 sampling locations were extracted from the DEM-derived topographic metric maps. Because some of the topographic metrics were highly correlated, PCA and varimax rotated FAn were applied to convert to mutually independent topographic combinations to reduce errors caused by collinearity between the metrics. The first six principal components (TPCs) and the first six factors (TFAs) were selected to develop isoscape models.

Models including the multiple linear regression (MLR) combined with principal component analysis (MLR-PCA) and MLR combined with factor analysis (MLR-FAn) models for SOC, $^{137}$Cs, and $\delta^{13}$C were developed using stepwise linear regression with the “leave-one-out” cross-validation. We randomly selected 70% samples...
Three criteria are the adjusted coefficient of determination ($R_{adj}^2$), the Nash-Sutcliffe efficiency (NSE), and ratio of the root mean square error (RMSE) to the standard deviation of measured data (RSR). Usually, the model performance is considered satisfactory when NSE is larger than 0.5 and RSR is smaller than 0.7 [69].

### 5.3 Results and discussion

#### 5.3.1 Soil redistribution impacts on C dynamics

Distribution of mollic epipedon, characterized by presence of black soil organic matter, reflected historical soil movement (Figure 4). The top-layer black soil

as training dataset used for model calibration and 30% samples as testing dataset for model validation. Three criteria were used to evaluate model efficiencies. The three criteria are the adjusted coefficient of determination ($R_{adj}^2$), the Nash-Sutcliffe efficiency (NSE), and ratio of the root mean square error (RMSE) to the standard deviation of measured data (RSR). Usually, the model performance is considered satisfactory when NSE is larger than 0.5 and RSR is smaller than 0.7 [69].
presumably blanketed the prairie landscape and was then transported by water and tillage from eroded upslope to downslope locations. This phenomenon can be observed from the higher mollic epipedon in the concave than the convex locations in the 1950s and likely more consolidated by 2002. The significant correlations between greyness values and $^{137}$Cs-derived soil redistribution rate suggested that $^{137}$Cs inventory can effectively reflect the soil redistribution process in this field.

The cropland experienced a general soil export as indicated by a negative mean $^{137}$Cs-derived soil redistribution rate ($-0.51 \pm 2.09 \, \text{kg} \, \text{m}^{-2} \, \text{year}^{-1}$, Table 2). Specifically, about 81 locations were identified as eroded sites with negative soil redistribution rates (mean: $-1.72 \pm 1.38 \, \text{kg} \, \text{m}^{-2} \, \text{year}^{-1}$) and 47 locations were depositional sites with positive soil redistribution rates (mean: $1.57 \pm 1.32 \, \text{kg} \, \text{m}^{-2} \, \text{year}^{-1}$).

SOC density exhibited a similar spatial pattern as soil redistribution rates with a higher mean value at depositional than eroded sites. The mean SOC density at depositional sites was about 1.70 times of that at eroded sites.

A strong and significant correlation was observed between $^{137}$Cs-derived redistribution rates and SOC density ($r^2 = 0.667$, Figure 5a), which demonstrated that $^{137}$Cs inventories can capture spatial patterns of SOC. The positive relationship between soil redistribution and SOC density is mainly caused by the preferential removal of C during soil erosion. The SOC is primarily concentrated on the topsoil layer and is prone to transport through runoff, wind, and tillage activities due to its low density. Silt and clay density that were enriched in SOC showed lower values at eroded sites than depositional sites could also provide evidence for the preferential movement of low-density particles [29].

Note that SOC mineralization and dynamic replacement can complicate impacts of soil redistribution on SOC. On the one hand, SOC mineralization highly depends on soil moisture conditions. Impacted by soil texture, soil moisture is commonly lower at upslope areas than low-lying areas. Our study area also showed similar spatial patterns in soil texture over the landscape [29]. The decreased fine particles...

†Letters (a and b) estimate based on Duncan’s multiple range tests. There are no significant ($p < 0.05$) differences for a parameter with the same letter.

Means of $\delta^{13}$C showed opposite spatial patterns with SOC and $^{137}$Cs-derived soil redistribution rates with a higher mean value of $\delta^{13}$C at eroded than depositional sites. The mean $\delta^{13}$C value at the eroded sites was $−19.6 ± 2.05\%$; while the $\delta^{13}$C value at the depositional sites was $−21.9 ± 1.52\%$. The higher mean $\delta^{13}$C value at eroded sites indicated that the eroded sites were less depleted for $^{13}$C and exhibited stronger C4 vegetation characteristics than depositional sites. The $\delta^{13}$C value variability over this space possibly resulted from dynamic replacement. Our study area was dominated by prairie vegetation with strong C3 vegetation characteristics before the 1850s. After that, C4-derived SOC was introduced as a new SOC formation into the soil due to the widespread maize cultivation [70]. The new soil C (C4-derived SOC) replaced 50% of native soil C (C3-derived SOC) at eroded sites and 30% at depositional sites till 2002 when sampled.

According to the calculations of the relative contributions of C3 and C4 crops to the SOC, the C3-derived SOC density showed a significant difference between eroded (396 ± 202 kg m$^{-2}$) and depositional sites (852 ± 226 kg m$^{-2}$) while the C4-derived SOC density varied insignificantly (Table 2, eroded: 363 ± 131 kg m$^{-2}$; depositional: 440 ± 152 kg m$^{-2}$). C3-derived SOC density was positively related to $^{137}$Cs-derived soil redistribution rates with a coefficient of determination of 0.65 (Figure 5b). In contrast, C4-derived SOC density was not strongly related to $^{137}$Cs-derived soil redistribution rates with a coefficient of determination of 0.317 (Figure 5c).

Figure 5.

to soil redistribution rates (Figure 5c). The different responses to soil erosion may be related to chemical compounds contained in the C3- and C4-derived SOC. Generally, liable compounds that are high in C4 crop residues are less depleted in $^{13}$C than lignin-based compounds that are high in C3 crop residues [71]. Therefore, C4-derived SOC may largely be found in the mollic epipedon and be significantly affected by C mineralization, resulting in a decreased correlation with patterns of soil movement. In contrast, the more recalcitrant SOC in soil with strong C3 vegetation characteristics would be less influenced by C mineralization because it contains higher amount of stable lignin-based compounds. Therefore, the variability in C3 signature of soil C would more strongly correlate with patterns of soil redistribution.

5.3.2 Isoscape model development

Based on the derived topographic metrics, the first six TPCs and six TFAs were selected to construct independent topographic variables. The metrics with the highest absolute loadings for the first six TPCs were TWI, TRPC2, FA, FPL, DI, and CA. Therefore, the TPCs 1, 2, 3, 4, 5, and 6 were associated with soil wetness, flow acceleration, runoff volume, flow velocity, downslope dispersal, and water volume, respectively [72]. The highest absolute loadings in the six TFAs were Upsl, G_Cur, Pl_Cur, FPL, CA, and DI, which were associated with upslope flow velocity, flow acceleration, flow convergence and flow divergence, flow velocity, water volume, and downslope dispersal, respectively.

SOC and isoscape models of $^{13}$C and $^{137}$Cs were developed using MLR-PCA and MLR-FAn (Table 3). Both types of models (MLR-PCA and MLR-FAn) presented satisfactory efficiencies during model calibration, but more independent variables were selected in MLR-FAn models. For SOC simulation, the MLR-PCA model selected four components with a $R^2_{adj}$ of 0.668, an NSE of 0.682, and an RSR of 0.563. The MLR-FAn model exhibited higher $R^2_{adj}$ and NSE values and a lower RSE value than MLR-PCA SOC model. In contrast, for $^{137}$Cs inventory and $^{13}$C simulations, similar $R^2_{adj}$ values were observed between the two types of models, but the MLR-FAn models showed higher NSE and RSR values, which suggested that the $^{137}$Cs and $^{13}$C values derived from MLR-FA models were less deviated from the corresponding observed values.

$^4$The order of variables is based on the stepwise selection steps. TPC and TFA are topographic principal component and topographic factor, respectively.

Table 3. Topography-based models for soil organic carbon (SOC), cesium–137 ($^{137}$Cs), and isotopic signature ($^{13}$C) in the cropland field.
Although both types of models reasonably matched up with observations during model calibration, the MLR-PCA models had better performance in predictions than the MLR-FAn models when applied to the test dataset. Predicted SOC explained 62.0% variability in observed SOC using MLR-PCA model. The values of NSE and RSR were 0.612 and 0.622, respectively. MLR-PCA $^{137}$Cs and $\delta^{13}$C models also had satisfactory performance with NSE values larger than 0.5 and RSR values smaller than 0.7. The $R^2$ for $^{137}$Cs and $\delta^{13}$C prediction were 0.713 and 0.509, respectively. In contrast, all the MLR-FAn models presented lower efficiencies in predicting target variables. Especially for the $\delta^{13}$C, the NSE value was smaller than 0.5 and RSR value was larger than 0.7 when compared MLR-FAn predictions with observations.

The lower efficiencies of the MLR-FAn models than the MLR-PCA models may be caused by model over-fitting. PCA considers all the variance in the independent variables, including unique, error and shared variance during synthetic variable construction; while FAn only considered and presented the shared variance in the factor matrix. Therefore, differences exist during development of MLR-PCA and MLR-FAn models. In this case study, although these two types of models had similar performance during model calibration using training datasets, increased number of parameters in MLR-FAn models may increase model error using validation datasets with general decrease in model stability, leading to low accuracies during extrapolating prediction points to external sample sets [73].

The spatial patterns of SOC density, $^{137}$Cs inventory, and $\delta^{13}$C were generated using MLR-PCA models (Figure 6). SOC density showed a similar spatial variability as $^{137}$Cs inventories, which is consistent with the strong correlations between the SOC density and $^{137}$Cs-derived soil redistribution rate (Figure 5a). Both variables had high values in depressions and low values in ridge and sloping areas. For $\delta^{13}$C, an opposite pattern was observed with low values in concave landscapes and high values in convex landscapes.

The high model efficiencies demonstrated the feasibility of using topography-based isoscape MLR-PCA models for investigating the spatial variability of isotopes. Although limitations may exist due to unaccounted topographic variables and environmental impactors, such as variance in tillage activities, the DEM-derived topography-based models provide a cost-effective method for isoscape mapping, effectively reflecting
redistribution patterns of soil and spatial patterns of SOC over the landscape [28, 74, 75]. These models can also benefit investigations in regions with limited access to ground measurements. The recently increased availability of the fine-resolution LiDAR data can further improve the model applicability, allowing for scaling of in situ isotopic simulations from field scale to isoscape mapping at watershed or regional scales.

6. Conclusions

Soil isotopes can effectively trace soil redistribution and SOC dynamics. This chapter reviewed the application of natural (7Be, 210Pb), anthropogenic fallout radionuclides (137Cs, 239,240Pu), and C isotopes (12,13,14C) in understanding soil erosion and deposition at different spatial and temporal scales. The case study demonstrated that 137Cs and C isotopes could be employed to understand soil movement and C dynamics. SOC density showed high consistency with 137Cs-derived soil redistribution rate, suggesting significant spatial impacts of soil movement on SOC. δ13C provided further support of the importance of dynamic replacement on soil C dynamics in this area. Topography-based isoscape models were developed and effectively reconstructed the spatial variability in 137Cs inventory and δ13C over the landscape. The isoscape maps of 137Cs and δ13C were in general agreement with the spatial pattern of SOC density. Based on such results, we conclude that isotopic and isoscape analysis could provide valuable insights into soil movement and C studies.

Chapter 2
Metamorphic Zircons Applied for Dating East African Tectono-Metamorphic Event in Central Mozambique

Vicente Albino Manjate

Abstract

The term East African is now used to describe the tectonic, magmatic, and metamorphic activity of Neoproterozoic to earliest Paleozoic age. Metamorphic zircon is the most suitable geochronometer for the determination of both protolithic and metamorphic ages due to its high closure temperature. The study area comprises the Mungari and Macossa-Chimoio nappes (Central Mozambique) tectonically juxtaposed to the Archaean Zimbabwe Craton. We use the metamorphic zircon morphology, Th/U ratios, and U-Pb ages to evaluate the Tectono-Metamorphic Event in central Mozambique. Morphologically, the zircon grains are sub-euhedral to euhedral, prismatic, with dark to gray cores, and narrow dark rims. The cores exhibit homogenous domains and oscillatory zoning. On the other hand, the U-Pb zircon data define Th/U ratios of 0.26–0.66 and 0.06–0.11. Finally, the U-Pb zircon analyses define upper intercept age of 1094 ± 36 Ma and lower intercept age of 498 ± 30 Ma. The zircon grains of the Macossa-Chimoio nappe was metamorphically re-homogenized or recrystallized by East African tectono-metamorphic event from relicts of Mesoproterozoic protolith domains. Thrusting and folding are the main East African reworking mechanisms that generated the metamorphic re-homogenization or recrystallization of the Mesoproterozoic magmatic rocks in the Macossa-Chimoio nappe of Central Mozambique.

Keywords: metamorphic zircon, protolith, East African, tectono-metamorphic, Macossa-Chimoio nappe, Mungari nappe

1. Introduction

Zircon is a fundamental secondary mineral of granitic rocks, very unsusceptible to sedimentary and metamorphic processes [1]. The term 'metamorphic zircon' is used to describe zircon that has formed in rocks under system-wide metamorphic conditions by a range of different processes [2]. According to [2], the main processes include precipitation from the melt during anatectic melting, sub-solidus nucleation and crystallization (blastogenesis) by diffusion of Zr and Si released from metamorphic breakdown reactions of major silicates and accessory phases,

Metamorphic Zircons Applied for Dating East African Tectono-Metamorphic Event in Central…
DOI: http://dx.doi.org/10.5772/intechopen.88514

The term East African is applied to illustrate the tectonism, magmatism, and metamorphism that took place on Neoproterozoic to earliest Paleozoic, mainly for a crust that was formally portion of Gondwana [3]. The term ‘East African’ was suggested by [4] supported on isotopic ages of Africa by Rb-Sr and K-Ar methods. According to [3], the East African was explained as a Neoproterozoic tectono-thermal event (~500 Ma) during which a number of mobile belts produced, bounding older cratons. This tectono-thermal event constitutes the final stage of an orogenic cycle, conducting to orogenic belts presently interpreted as a consequence of the fusion of continental blocks throughout the time interval from ~870 to ~550 Ma [3].

The study area comprises the nappes of Macossa-Chimoio and Mungari [5] (Figure 1). According to [5], the northern Mungari nappe is composed of metamorphic supracrustal rocks intruded by a set of granitoid plutons. On the other hand, the southern Macossa-Chimoio nappe is composed of orthomagmatic rocks covered by medium to high-grade supracrustal rocks. In addition, both nappe complexes include detrital zircon grains with Neoproterozoic age [6].

We use the metamorphic zircon morphology, Th/U ratios, and 207Pb/206Pb ages to evaluate the East African tectono-metamorphic event in Central Mozambique. Although the SHRIMP technique is very expensive, its advantages in comparison to other dating techniques are in favour of the geochronological data determination for this study (Table 1). One of the most important legacies of SHRIMP U-Pb dating on zircons is the extraction of crystallization and recrystallization ages of igneous protoliths from complexly deformed and metamorphosed lithologies.

2. Geological and tectonic setting

The study area (Figure 1) comprises rocks of the Neoproterozoic Mungari and the Mesoproterozoic Macossa-Chimoio nappes tectonically juxtaposed to the Archaean Zimbabwe Craton [5–7]. The Neoproterozoic Mungari nappe is composed of garnet gneiss-granite plutons of about 850 Ma intruding meta-sedimentary rocks consisting of marbles with calc-silicate interbeds [7]. This nappe is delimited on the west, north and east by Neoproterozoic (~850 Ma) bimodal Guro Suite and on

Table 1. Summary of the applicability, advantage, and disadvantage of the LA-ICP-MS, SHRIMP, and TIMS dating techniques.
the south by the Macossa-Chimoio nappe [7, 8]. The Mesoproterozoic Macossa-Chimoio nappe consists of medium-to-high-grade supracrustal rocks composed of quartz-feldspar gneiss, deformed granodiorite, deformed granite, garnetiferous leucocratic gneiss, meta-arkose with amphibolite, calc-silicate gneiss, feldspathic quartzite, and leucocratic gneiss [7, 8]. According to [8], in the north, the Macossa-Chimoio nappe terminates into a northward-directed arcuate thrust (Figure 1). For [8], the Macossa-Chimoio nappe consists of supracrustal rocks most likely derived from sedimentary precursors, originally deposited in a shallow marine paleobasin. Although the definitive character and position of all units observed within the supracrustal rocks succession are not fully solved, the overall lithostratigraphy of the paleobasin has been reduced by [8] from several geological sections made in the area [9, 10]. The lowermost rock units of the inferred paleobasin include garnetiferous leucocratic gneisses, quartz-feldspar gneisses, meta-arkoses, and arkosic quartzites. These psammitic metasediments are overlain by more pelitic rocks (metagreywackes, garnet, and sillimanite bearing mica schist and mica gneisses) with thin calc-silicate gneiss and marble interbeds.

The Macossa-Chimoio nappe is delimited by a number of structural domains. According to [8], the eastern margin of the Mesoproterozoic Macossa-Chimoio nappe is bounded by a set of rift faults/dykes ‘corridor’ against the Karoo and younger formations and partly remains covered by recent sediments, the western margin is a major N-S directed sinistral shear zone along the Archaean cratonic margin, in the north the nappe terminates into a northward-directed thrust, and in the south the rocks of the nappe become covered by Phanerozoic beds. According to [8], the northward thrusting of the northern part of the Macossa-Chimoio nappe over the Mungári nappe gneisses may be attributed to the East African collision, the sinistral shearing is a regional feature in the East Africa orogeny, and the set of rift faults/dykes ‘corridor’ against the Karoo and younger formations are normal faults with dip values commonly ranging from 45 to 60°.

The granitic pluton (deformed granite) selected for this study is located at the northern end of the Macossa-Chimoio nappe and was emplaced parallel to the foliation of the host gneisses and migmatites. The rock is a pinkish to pinkish gray, medium- to coarse-grained, weakly deformed leucogranite and is mainly composed of quartz, pinkish potassium feldspar, plagioclase, hornblende, and biotite. Accessory minerals include garnet, clinopyroxene, orthopyroxene, zircon, apatite, and opaques.

3. Analytical procedures

Zircon dating analyses by sensitive high-resolution ion microprobe (SHRIMP) U-Pb were performed at the São Paulo University, Brazil. This technique is very important for geochronological studies [11] as it permits in situ analyses of complex zircons grains often exhibiting several crystallization phases associated with different geological processes [12]. According to [12], the SHRIMP technique has an improving spatial resolution for dating with precision the different growth episodes on single zircon grains. Zircon crystals were separated utilizing the common manually breaking, crushing and grinding of samples, followed by grain size separation by sieving. The material (100–200 mesh portion) was deposited on a vibrating Wilfley table, and heavy minerals were then densimetrically separated using bromoform (d = 2.89 g/ml; 20°C) and methylene iodide (d = 3.32 g/ml; 20°C). The dense material (density above 3.32 g/ml) was then electromagnetically separated using a Frantz separator. The magnetic minerals were separated using a hand magnet and the paramagnetic minerals were separated by a Frantz
magnetic separator (amperage variation). Zircon crystals are concentrated in the non-magnetic portion. Zircon crystals along with zircon standards were picked by hand, impregnated in epoxy resin mounts with a diameter of 2.54 cm, ground and polished with diamond compound (1–7 μm) to reveal grain centers and carbon coated as well as cleaned and gold-coated in preparation for the SHRIMP analyses. Reflected and transmitted light images (Figure 2) were acquired before the gold coating of 2–3 μm. Zircons internal structures were microphotographed in transmitted and reflected light and characterized by the use of cathodoluminescence (CL) images from scanning electron microscope prior to SHRIMP U-Pb zircon isotopic analyses. CL images of representative zircon crystals can be seen in Figure 3. After CL acquisition, the gold was removed and the mount was re-cleaned. The U-Pb zircon dating analyses were made using a SHRIMP IIe/MC mass spectrometer.
Table 2.
Analytical data for zircons from the deformed granite, Macossa-Chimoio nappe.
4. Results and discussions

4.1 Zircon morphology and internal structure

Zircon morphology and internal structure provide an important tool for discerning their growth stages and genesis. Zircons of our study are products of anatectic melt, altered by metamorphic fluid and hydrothermal alteration. Anatectic melt, metamorphic fluid, and hydrothermal alteration are important factors controlling the morphology and internal structure of zircons overgrowths [17]. Zircons crystallizing from anatectic melts also have a euhedral shape with no zoning, planar zoning or oscillatory zoning. In addition, zircons altered by the metamorphic fluid
are usually homogenous with high CL intensity, showing resorption structure. Moreover, zircon domains that lost all radioactive Pb during hydrothermal alteration always show white color in CL image. The study made on deformed granite showed that the zircon grains are inherited from older crustal rocks or metamorphically re-homogenized or recrystallized from relicts of magmatic protolith domains. These zircon grains range in size from 250 to 400 μm of length, and 125 μm of width with length/width ratios of 2.1–3.2:1. In addition, they are colorless and transparent (Figure 2), sub-euhedral to euhedral with elongated prismatic shapes. Moreover, these zircon grains exhibit narrow dark rims and dark to gray cores with some homogenous domains and other domains of compositional or oscillatory zoning (Figure 3), being thus strongly re-homogenized. Therefore, the zircons of our study are products of anatectic melts or altered by metamorphic and hydrothermal fluids.

4.2 Genesis and recrystallization of the metamorphic zircons

Sixteen analyses spots (cores and rims) in 14 zircon grains from the deformed granite for Th/U ratios and 207Pb/206Pb ages determinations (Table 2). These analyses spots define two groups based on Th/U ratios and apparent 207Pb/206Pb ages. The first group is defined by cores with U grades from 110 to 472 ppm (averaging 242 ppm) and Th ranging from 55 to 165 ppm (averaging 104 ppm). This result in Th/U ratios from 0.26 to 0.66 and 207Pb/206Pb ages varying from 872 ± 31 to 1136 ± 19 Ma. The other group is represented by rims with U grades ranging from 860 to 942 ppm (average of 890 ppm) and Th ranging from 56 to 95 ppm (average of 80 ppm). This result in Th/U ratios from 0.06 to 0.11 (average of 0.09) and 207Pb/206Pb ages varying from 510 ± 23 to 542 ± 16 Ma. The age data follow a regression line (Figure 4) that allowed to determine the upper intercept age of 1094 ± 36 Ma and lower intercept age of 498 ± 30 Ma (MSWD = 1.07).

Th/U ratios are used as indicators of zircon types. The Th/U ratios of magmatic zircons are commonly between 0.32 and 0.70, whereas hydrothermal zircons frequently have more extreme values [18–20]. Proposed that Th/U ratios <0.1 are probably a hint for hydrothermal origin. Therefore, the studied zircons are products of metamorphic re-homogenization or recrystallization from relicts of magmatic protoliths.

The studied metamorphic zircons registered two events. The magmatic protolith domains crystalized at ~1094 ± 36 Ma. This was followed by re-homogenization or recrystallization related to northward-directed thrusting and folding at ~498 ± 30 Ma of the Chimoio-Macossa nappe [5]. Using LA-ICP-MS U/Pb zircon for leucocratic gneiss (sample 14FR09, Figure 1) of Chimoio-Macossa nappe found 207Pb/206Pb crystallization age of 1067.8 ± 9.0 Ma and a metamorphic age of 504 ± 1.8 Ma. These age determinations are in accordance with that of [21] for the Macossa-Chimoio nappe. According to Yuanbao (2004), the time of metamorphic recrystallization is represented by the age of recrystallized zircon domain with the lowest Th/U ratio and the youngest U-Pb age.

The Cambrian U-Pb ages are found in both cores and rims of the Mesoproterozoic Macossa-Chimoio nappe rocks. Manjate [22] found a Neoproterozoic-Cambrian recrystallization age (498 ± 19–562 ± 14 Ma) on zircon cores of the Dongueni Mount nepheline syenite generated from partial melting of Mesoproterozoic crust, as shown by inherited zircon ages of 1040 ± 14 (15) Ma. The Cambrian magmatism, defined by zircon U-Pb dates of c. 490 Ma, from Dongueni Mount nepheline syenite, southeast of Chimoio village [23], is post-collisional and marks the end stage of East African Orogeny. Therefore, zircons are suitable for dating the tectono-metamorphic Neoproterozoic-Cambrian event that affected the Macossa-Chimoio nappe. The Neoproterozoic-Cambrian recrystallization ages on zircon were the common determinations made by a number of authors [23–26].
5. Conclusions

Zircons are appropriate for dating the tectono-metamorphic Neoproterozoic-Cambrian event that affected the Macossa-Chimoio nappe. The studied zircon grains exhibit narrow dark rims and dark to gray cores with some homogenous domains and other domains of compositional or oscillatory zoning, as well as, Th/U ratios less than 0.3 which are evidence of metamorphic re-homogenization or recrystallization from relicts of magmatic protolith domains.

Thrusting and folding are the main East African Neoproterozoic-Cambrian reworking mechanisms (ca. 498 ± 30 Ma) that generated the metamorphic re-homogenization or recrystallization of the Mesoproterozoic magmatic rocks (ca. 1094 ± 36 Ma) in the Macossa-Chimoio nappe of Central Mozambique.

Abstract
Evaporite minerals record the hydrogeochemical conditions in which they precipitated. And therefore they can be used to reconstruct the paleoclimate and paleoenvironments. Evaporite minerals are also major sources of industrial minerals including gypsum, halite, borates, lithium concentrates, and others. Because of their scientific significance and economic importance, evaporite minerals and their isotopic hydrochemical processes linked to their formation have been the focus of many geologists and paleoclimatologists. This chapter will discuss the application of isotopes of hydrogen, oxygen, sulfur, strontium, and boron in saline conditions. This will include the following: the $\delta^{18}O$ and $\delta^D$ of hydrated water of gypsum and their paleoclimate since 2.2 Ma in the Qaidam Basin, NE Tibetan Plateau; the $\delta^{18}O$ and $\delta^D$ of the interlayer water of clay minerals in salar lacustrine sediments; and the $^{87}Sr/^{86}Sr$, $\delta^{34}S$, and $\delta^{11}B$ of halite from evaporite deposits in Khorat Plateau, Laos, and Yunnan and their application in the origins of brine.

Keywords: oxygen and hydrogen, Sr isotope, sulfur isotope, boron isotope, salt minerals

1. Introduction
Evaporite minerals record the hydrogeochemical conditions in which they precipitated. And therefore they can be used to reconstruct the paleoclimate and paleoenvironments. Evaporite minerals are also major sources of industrial minerals including gypsum, halite, borates, lithium concentrates, and others. Given their scientific significance and economic importance, evaporite minerals and their isotopic hydrochemical processes linked to their formation have become the focus of many geologists and paleoclimatologists. The Qaidam Basin and Lanping-Simao Basin (LSB) in China and Khorat Basin (KB) and Sakhon Nakhon Basin (SNB) in Thailand and Laos, which have thick sequences of evaporites, have been the focus of study by researcher concerned with its mineral resources, geochemistry, paleoenvironmental evolution, and tectonic uplift [1–3].

Water is nearly ubiquitously in nature. Its isotopic compositions also were recorded in many minerals. In order to identify the past conditions at which sediments formed, many studies focused on the stable isotopes of carbon and oxygen as tracers of environmental conditions. However, we know little about the $\delta^{18}O$ and $\delta^D$ in saline conditions. On the other hand, halite and gypsum are two common minerals in evaporite deposits. 1. Introduction

Evaporite minerals record the hydrogeochemical conditions in which they precipitated. And therefore they can be used to reconstruct the paleoclimate and paleoenvironments. Evaporite minerals are also major sources of industrial minerals including gypsum, halite, borates, lithium concentrates, and others. Given their scientific significance and economic importance, evaporite minerals and their isotopic hydrochemical processes linked to their formation have become the focus of many geologists and paleoclimatologists. The Qaidam Basin and Lanping-Simao Basin (LSB) in China and Khorat Basin (KB) and Sakhon Nakhon Basin (SNB) in Thailand and Laos, which have thick sequences of evaporites, have been the focus of study by researcher concerned with its mineral resources, geochemistry, paleoenvironmental evolution, and tectonic uplift [1–3].

Water is nearly ubiquitous in nature. Its isotopic compositions also were recorded in many minerals. In order to identify the past conditions at which sediments formed, many studies focused on the stable isotopes of carbon and oxygen as tracers of environmental conditions. However, we know little about the $\delta^{18}O$ and $\delta^D$ in saline conditions. On the other hand, halite and gypsum are two common minerals in evaporite deposits. Today, exploited evaporite deposits are most found
in the arid and semiarid deserts of the world (the areas between latitudes 15° and 45° both north and south of the equator). Tectonics, climate, and origins of brine are the prime controls on most evaporite deposits. However, the origins of brine was a big topic for some giant evaporite deposits, for example, the evaporite deposit in Khorat Basin (KB) in Thailand, Sakhon Nakhon Basin (SNB) in Laos, and Lanping-Simao Basin (LSB) in China. Almost all large potash deposits are associated with marine fluids (such as the deposits in Thailand, the United States, Germany, Russia, France, and Brazil), whereas some small potash deposits are with fluids of continental source (such as deposits in the Qaidam Basin, Western Tibet, China) [1, 2]. The isotopes of S, Sr, and B of halite could be very useful in determining the origins of brine. So this chapter will use well-known accepted methods to analyze minerals (halite, gypsum, and clay minerals) and stable isotopes (δ¹⁸O and δD, ⁸⁷Sr/⁸⁶Sr, δ³⁴S, and δ¹¹B) to discuss their application in paleoclimate and origins of brine.

2. The δ¹⁸O and δD in saline conditions

2.1 Geological setting and the Core SG-1 in the Qaidam Basin, NE Tibetan Plateau

The Qaidam Basin is a Mesozoic-Cenozoic sedimentary basin located on the northern margin of the Tibetan Plateau in China (Figure 1). The Asian inland drought basin was formed as the result of intracontinental deformation and plateau uplift due to the collision of the Indian and Eurasian Plates. It is bordered by the Kunlun Mountains to the south, the Qilian Mountains to the northeast, and the Arjin Mountains to the northwest, which have altitudes ranging from 4000 to 4500 m asl to over 5000 m asl. A network of faults exists within the basin [3]. The Paleogene and Neogene strata are widespread and include intrusive rocks. From the Middle Oligocene to the Upper Pliocene, the strata consist of mudstones, calcareous mudstones and marls, intercalating siltstone, very thick gypsum, and rock salt beds in the western basin [4]. Some secondary or subsidiary basins have become well developed since the Middle Pleistocene as a result of slow uplift [1]. Lacustrine sediments in

![Figure 1](http://example.com/figure1.png)

Figure 1.
Map of the Qaidam Basin showing the core site.
the basin cover an area of 30,000 km² with strata up to 700 m thick [4]. Abundant records of palaeo-lake level and paleoclimatic changes are indicated by various proxies, such as pollen, ostracods, evaporite minerals, and isotopic geochemistry [5, 6]. Studies on evaporite minerals and hydrochemistry and geochemistry of salt lakes have been ongoing for about 50 years because of great economic significance [1, 2, 5, 7]. However, no two drainage basins have identical climatic and hydrologic conditions, and even adjacent basins can show striking variations in evaporite mineralogy [8].

The Core SG-1 (38°24′35.3″ N, 92°30′32.7″ E, 2900 m asl) was located in a playa in the Qahansilatou sub-basin, western Qaidam Basin (Figure 1). The core spanned from 2.77 to 0.1 Ma, dated by paleomagnetism and optically stimulated luminescence (OSL) with a sedimentary rate of 26.1–51.5 cm/ka [9]. The sedimentary sequence is composed of clay, clay-silt, and siltstone intercalated with salt layers (mainly halite), marl beds, and thin and/or scattered gypsum crystals, indicating clay-silt and halite-marl depositional cycles (Figure 2). The fluctuation between evaporite minerals and carbonaceous clay strata indicates a shift between dry and wet climates. Gypsum and halite make up the majority of the evaporite minerals in the core [11, 12]. During the last ~2.8 Ma, the lake basin evolved from a semi-deep fresh lake to a semi-brackish lake (2.8–2.2 Ma), to a perennial saline lake (2.2–2.0 Ma), to a shallow brackish lake (1.8–1.6 Ma), to a perennial saline lake (1.2–0.6 Ma), to a playa saline lake (0.9–0.6 Ma), and to a saline mudflat (0.6–0.1 Ma) [10] (Figure 2). Multi-proxies, such as sedimentary features [10], salt minerals [11], isotope records [13, 14], and rare earth elements [15] of the study area, indicate the long-term persistent aridification of inland Asia since 2.8 Ma.

2.2 Clay minerals and the $\delta^{18}O$ and $\delta D$ of their interlayer water

2.2.1 Clay minerals

Clay minerals have been used to reconstruct paleoclimates and environments since Singer’s review in 1984 [16]. It is common that the clay minerals undergo...
diagenetic transformations or postdepositional diagenetic changes, and as a result, some paleoclimate information of clays will be overprinted or changed. However, there are still lots of studies to use clay minerals to reconstruct paleoenvironments and paleoclimates. The isotopic exchange rates between the interlayer water of clay minerals and the ambient water are very fast and, in general, are less than a few days. However, in saline conditions, we know little about the isotopic exchange between them.

The clay mineral assemblages in the Core SG-1 are shown in Figure 3. The curves of chlorite and illite abundances are similar, but they are different with those of the kaolinite, smectite, and I/Sm (Figure 3). The curve of smectite content shows a decreasing trend with decreasing depth, and that of the illite content shows an increasing trend slightly (Figure 3). The XRD analyses suggest that the I/Sm in the core exhibits order (R3 I/Sm) (mixed layer of I/Sm > 80%). R1 I/Sm is more stable than any other mixed layer I/Sm phase because it has a unique structure, composition, and order [17]. The clay minerals that were identified as R1 I/Sm by XRD analyses are possible to be mixtures of discrete smectite and R1 I/Sm [17].

The diagenesis of clay minerals in lacustrine sediments is a disputed topic. The clays in Core SG-1 in the Qaidam Basin probably underwent early diagenesis based on their curves and relationship between them (Figures 4 and 5) [18]. Climate changes, to some extent, control on the degree of alteration of the primary minerals and the composition of the secondary products. In the clay minerals, the exchange between the interlayer water and the ambient water recorded the diagenetic information. For instance, the δ18O and δD of the different clays and interlayer water record temperatures that range from surface temperatures to hydrothermal temperatures of about 150–200°C [19]. In situ precipitation of I/Sm minerals may take place in chemical and isotopic equilibrium with the reacting solution [20, 21]. However, in high saline conditions, the reaction or the above exchange may be extremely slowly.

2.2.2 The δ18O and δD of the interlayer water

The δ18O of the interlayer water ranged from −11.8 to 82.95% with the average of 20.8%, and the δD ranged from −114.3 to 165.5% with the average of −35.6%

Isotopic Application in High Saline Conditions

The clay mineral assemblages in the Core SG-1 are shown in Figure 3. The curves of chlorite and illite abundances are similar, but they are different with those of the kaolinite, smectite, and I/Sm (Figure 3). The curve of smectite content shows a decreasing trend with decreasing depth, and that of the illite content shows an increasing trend slightly (Figure 3). The XRD analyses suggest that the I/Sm in the core exhibits order (R3 I/Sm) (mixed layer of I/Sm > 80%). R1 I/Sm is more stable than any other mixed layer I/Sm phase because it has a unique structure, composition, and order [17]. The clay minerals that were identified as R3 I/Sm by XRD analyses are possible to be mixtures of discrete smectite and R1 I/Sm [17].

The diagenesis of clay minerals in lacustrine sediments is a disputed topic. The clays in Core SG-1 in the Qaidam Basin probably underwent early diagenesis based on their curves and relationship between them (Figures 4 and 5) [18]. Climate changes, to some extent, control on the degree of alteration of the primary minerals and the composition of the secondary products. In the clay minerals, the exchange between the interlayer water and the ambient water recorded the diagenetic information. For instance, the $\delta^{18}$O and $\delta^D$ of the different clays and interlayer water record temperatures that range from surface temperatures to hydrothermal temperatures of about 150–200°C [19]. In situ precipitation of I/Sm minerals may take place in chemical and isotopic equilibrium with the reacting solution [20, 21]. However, in high saline conditions, the reaction or the above exchange may be extremely slowly.

2.2.2 The $\delta^{18}$O and $\delta^D$ of the interlayer water

The $\delta^{18}$O of the interlayer water ranged from $-11.8$ to 8.95% with the average of 20.8%, and the $\delta^D$ ranged from $-114.3$ to 165.5% with the average of $-35.6%$.
2.3 Gypsum and the $\delta^{18}O$ and $\delta D$ of hydrated water

### 2.3.1 Gypsum

Gypsum (CaSO$_4$$\cdot$2H$_2$O), one of the most abundant evaporite minerals occurring as a syndepositional evaporite, carries information about brines from which they precipitate. There are several shapes of gypsum crystals (Figure 6). These prismatic and tabular gypsum layers were vertically aligned, indicating primary subaqueous precipitates and with bottom nucleation [31, 32]. Some euhedral gypsum crystals were scattered in the mudstone-siltstone layers, which are possibly formed by evaporation of pore water or interstitial brine and regarded as diagenetic gypsum. Based solely on their morphology, it is not easy to confirm gypsum to be syngenetic or diagenetic, because there is no diagnostic relationship between crystal morphology and depositional environment [33]. Besides the aligned gypsum, scattered euhedral crystals may be significant for understanding the evolution of lake water, because pore water or interstitial brine may have originated from infiltration of lake water. The Core SG-1 showed an increase of evaporite mineral contents upward, and the strata were mainly horizontal and not affected by tectonic deformation [10]. Therefore, these selected gypsiums may have been primary in origin in arid, or aqueous, young lacustrine. These environments contain deposits that have never been exposed or deeply buried and may also retain their original isotopic compositions [34–36].

Minor cations such as Sr$^{2+}$, K$^+$, and Mg$^{2+}$ may be incorporated into gypsum lattice via substitution for Ca$^{2+}$ during the coprecipitation process because they have similar ionic radii. Different cations are selectively attracted to particular faces [37, 38]. For example, the (1 1 1) face is covered by either calcium ions or sulfate clusters and the (1 1 0) and (0 1 0) faces by both calcium and sulfate clusters [39]. Na$^+$ is preferentially adsorbed on (1 1 1) surface of sulfate salts that is dominantly occupied by Ca$^{2+}$ [39, 40]. However, the presence of Na$^+$ also impedes the (1 1 1) face growth and, as a result, minimizes parallel to its c axis [36, 39]. K$^+$ has a similar inhibitory effect [40]. Because of the difference in coordination number between Ca$^{2+}$ (eight in gypsum) and Mg$^{2+}$ (six in most minerals), Mg$^{2+}$ will disturb gypsum growth and, as a result, minimizes parallel to its c axis [36, 39]. K$^+$ has a similar inhibitory effect [40]. Because of the difference in coordination number between Ca$^{2+}$ (eight in gypsum) and Mg$^{2+}$ (six in most minerals), Mg$^{2+}$ will disturb gypsum growth and, as a result, minimizes parallel to its c axis [36, 39]. K$^+$ has a similar inhibitory effect [40]. Because of the difference in coordination number between Ca$^{2+}$ (eight in gypsum) and Mg$^{2+}$ (six in most minerals), Mg$^{2+}$ will disturb gypsum growth and, as a result, minimizes parallel to its c axis [36, 39]. K$^+$ has a similar inhibitory effect [40]. growth along c axis [41]. Preferentially adsorbed on the (1 1 0) face, Sr²⁺ forms epitaxial deposits of strontium sulfate [39]. Therefore, K⁺, Na⁺, and Mg²⁺ make the c value smaller, while Sr²⁺ reduces a and b values. As a result, there have different gypsum morphologies.

### 2.3.2 The δ¹⁸O and δD of hydrated water

The δ¹⁸O of gypsum hydrated water ranged from −4.21 to 8.69%, with average of 5.74%; and the δD was from −72.77 to 49.73%, with average of −28.09%. They exhibit a roughly linear relationship with the slope of 5.39, and its mother water-line has a slope of 5.52 (Figure 7). The δ¹⁸O and δD appear to be much lower than those of today’s mean precipitation (δ¹⁸O = −9.25% and δD = −41.3%) [14]. This indicated a slightly weaker evaporation and/or colder climate than today [36, 43]. On the other hand, the δ¹⁸O and δD are close to those of the Altyn Tagh Mountain groundwater that sourced from meteoric water (Figure 7). It is therefore likely that meteoric water was the main source of hydration water during gypsum formation.

In general, gypsum could be formed in the following ways: in situ formation (e.g., resulting from the oxidation of sulfide minerals); hydration of anhydrite; and direct deposition from an evaporating solution saturated with gypsum [44]. If gypsum was formed in situ formation, the δ¹⁸O and δD of hydrated water would reflect those of meteoric and/or surface waters [44, 45]. If it is formed from the hydration of anhydrite, which is assumed to be a Rayleigh process, both the hydration water and its mother water would be expected to move along a line with a negative ΔδD/Δδ¹⁸O [46, 47]. In this study, the ΔδD/Δδ¹⁸O value was 5.39 [14], suggesting evaporation to be the major geochemical process for gypsum deposition, that is, the gypsum in the Core SG-1 was likely to deposit directly from brines. The degree

---

**Figure 6.**

The monoclinic gypsum exhibits four principal forms in the Core SG-1 [30]: prismatic crystals, lenticular crystals, and tabular crystals. The tabular and prismatic crystals tend to increase with decreasing depth. The red numbers mean that the same kind of crystal morphology can appear in different environments and different crystal morphologies can also occur in the same depositional environment.

---

**Figure 7.**

The δ¹⁸O and δD of hydrated water exhibit a roughly linear relationship with the slope of 5.39, and its mother water-line has a slope of 5.52. The δ¹⁸O and δD appear to be much lower than those of today’s mean precipitation (δ¹⁸O = −9.25% and δD = −41.3%) [14]. This indicated a slightly weaker evaporation and/or colder climate than today [36, 43]. On the other hand, the δ¹⁸O and δD are close to those of the Altyn Tagh Mountain groundwater that sourced from meteoric water. It is therefore likely that meteoric water was the main source of hydration water during gypsum formation.
of evaporation depends upon the salinity and atmospheric humidity [22, 48]. In humid conditions, $\Delta \delta D/\Delta \delta^{18}O$ gradients are usually between ~5 and ~6, whereas the gradient can be low as 2.5–4 in arid regions. The evaporation line gradient for present-day Qaidam Basin meteoric water is lower 4.4 [24], which is less than that of gypsum hydration water in Core SG-1. This suggested that brine in the 2.2–0.1 Ma had lighter isotopes than today’s local meteoric water and that evaporation was weaker than today’s.

2.4 Paleoclimatic implications

The climate in the area indicates a long-term persistent aridification event in inland Asia, which is supported by several climate proxies [10–15]. The $\delta^{18}O$ and $\delta D$ of the clay interlayer water and gypsum hydrated water both reflect the compositional variations of the lake water or pore water and record changes in environment [14, 18]. According to the significant positive relationship between $\delta^{18}O$ and $\delta D$ and their low slope (2.933, Figure 7), most of the interlayer water could be from pore water and lake water in an evaporative environment. The main factor contributing to the variations in the $\delta^{18}O$ and $\delta D$ water was probably E/P value oscillations, which were linked to the climate changes.

Both the lake water and gypsum hydrated water, their curves of the $\delta^{18}O$ and $\delta D$, display a stepwise increasing trend (Figure 8), indicating a drying trend from 2.2 to 0.1 Ma. This is consistent with the global cooling trend, which is also recorded by the $\delta^{18}O$ of marine sediments (Figure 8). The lower values of $\delta^{18}O$ and $\delta D$ in 1.2–0.1 Ma than in 2.77–1.2 Ma (Figure 8) agreed with the sedimentary changes from brackish lakes to saline and playa lakes [10]. Compared with brackish lakes, it is harder for brines in mudflat and playa lakes to lose water. The occurrence of Na$_2$SO$_4$-bearing salt minerals such as glauberite, thenardite, mirabilite, and bloedite [11] and the high $\delta^{18}O$ of carbonates [13] also suggest the climate to be extremely...
Isotopes Applications in Earth Sciences

46

The evaporation of water depends upon the salinity and atmospheric humidity [22, 48]. In humid conditions, \( \Delta \delta^D / \Delta \delta^{18}O \) gradients are usually between ~5 and ~6, whereas the gradient can be low as 2.5–4 in arid regions. The evaporation line gradient for present-day Qaidam Basin meteoric water is lower 4.4 [24], which is less than that of gypsum hydration water in Core SG-1. This suggested that brine in the 2.2–0.1 Ma had lighter isotopes than today’s local meteoric water and that evaporation was weaker than today’s.

2.4 Paleoclimatic implications

The climate in the area indicates a long-term persistent aridification event in inland Asia, which is supported by several climate proxies [10–15]. The \( \delta^{18}O \) and \( \delta^D \) of the clay interlayer water and gypsum hydrated water both reflect the compositional variations of the lake water or pore water and record changes in environment [14, 18]. According to the significant positive relationship between \( \delta^{18}O \) and \( \delta^D \) and their low slope (2.933, Figure 7), most of the interlayer water could be from pore water and lake water in an evaporative environment. The main factor contributing to the variations in the \( \delta^{18}O \) and \( \delta^D \) water was probably E/P value oscillations, which were linked to the climate changes.

Both the lake water and gypsum hydrated water, their curves of the \( \delta^{18}O \) and \( \delta^D \), display a stepwise increasing trend (Figure 8), indicating a drying trend from 2.2 to 0.1 Ma. This is consistent with the global cooling trend, which is also recorded by the \( \delta^{18}O \) of marine sediments (Figure 8). The lower values of \( \delta^{18}O \) and \( \delta^D \) in 1.2–0.1 Ma than in 2.77–1.2 Ma (Figure 8) agreed with the sedimentary changes from brackish lakes to saline and playa lakes [10]. Compared with brackish lakes, it is harder for brines in mudflat and playa lakes to lose water. The occurrence of Na₂SO₄-bearing salt minerals such as glauberite, thenardite, mirabilite, and bloedite [11] and the high \( \delta^{18}O \) of carbonates [13] also suggest the climate to be extremely arid in 1.2–0.1 Ma. At about 1.2–1.1 Ma, the low value was likely due to the MPT cold event, which was also recorded in other places in the Qaidam Basin [49]. This is also consistent with other proxies in Central Asia such as lithological and sedimentary records, evaporative minerals, pollen records, grain size, and trace elements [10–13, 49–51].

In summary, \( \delta^{18}O \) and \( \delta^D \) of the gypsum hydrated water, and interlay water of clay in high saline conditions, both have recorded environmental signals.

3. The isotopes of Sr, S, and B of halite in saline conditions

Halite is common in evaporite deposits. Today, exploited evaporite deposits are most found in the arid and semiarid deserts of the world (the areas between latitudes 15° and 45° both north and south of the equator). Tectonics, climate, and origins of brine are the prime controls on most evaporite deposits. However, the origins of brine were a big topic. Giant evaporite deposits typically originate from brines with a marine or/and land origin(s), along with varying inputs from deeply circulated meteoric, basinal, and hydrothermal fluids [52]. The isotopes of S, Sr, and B of halite could be very useful in determining the origins of brine. We used well-known accepted methods to analyze halite and the isotopes to distinguish origins of brine for the evaporite deposits in Laos and Southern China.

3.1 Geological setting and the Core ZK2893

3.1.1 Geological setting in Laos and Southern China

Southeast Asia is composed of a series of Gondwana-derived continental blocks which experienced heterogeneous collision with the closure of multiple Tethyan Ocean branches (see reviews in Metcalfe [53, 54]). The Khorat Basin (KB) in Thailand and Sakhon Nakhon Basin (SNB) and the Lanping-Simao Basin (LSB) in Southwest China belong to the Indochina Block (Figure 9). The central part of the
Indochina Block (the Khorat Plateau) is relatively rigid with respect to the Simao Terrane (including the LSB) and has been experiencing clockwise rotation of about 15° up to the present day [58, 59]. The location of LSB changed from 25.7° N in Cretaceous to 18.6° N in Paleocene and Eocene [60]. This suggested that the LSB was gradually southward approaching the KB and SNB.

During the Middle and Late Cretaceous, salts formed; however, these salt formations lie atop thick nonmarine sediments of the Mesozoic Khorat Group. The nonmarine sediments were more than 5 km thick, which were deposited in the Late Triassic [56, 61, 62]. From the very Late Triassic to the Early Cretaceous, the KB and SNB were filled with fluvial and lacustrine facies [56]. Due to the occurrence of similar salt minerals within the same tectonic belt in KB and the LSB, they have formed in brines from similar sources [63].

In the mid-Cretaceous, the basins (LSB, KB, and SNB) were within the subtropical high-pressure belt [64]. However, the scale of the Mengye potash deposit in the LSB is much smaller than those in the KB and SNB of Thailand and Laos [63]. This surprising contrast drove many scientists to explore it in the area for ~50 years. But no consensus has therefore been reached regarding their fluid origins [56, 65, 66].
3.1.2 The Core ZK2893 in Laos

The lithostratigraphy contained three evaporite-clastic cycles, upper member (148.4 m to top), middle member (299.2–148.4 m), and lower member cycles (595.4–299.2 m), which are composed of evaporite unit and red-colored siliciclastic unit (Figure 10). The lithostratigraphy of the core could match with a reviewed section by El Tabakh et al. [56]. Blocky halite beds were only present in the lower and middle members (Figure 11). Chevron or cumulate crystals were well developed. Some thin salt units are observed (Figure 10), suggesting salt dissolution to be happened and their dissolved solutes to be mixed with their adjacent mudstone. Salt dissolution resulted in a lack of salts in many cores and the deposition of anhydrite [56].

3.2 Halite

The evaporite minerals in the halite beds are pure, massive red halite in ZK2893 (Figure 11). Some samples have trace or minor anhydrite content [60]. Compared with gypsum, the crystal shapes of halite seldom vary. But halite is much easier to be dissolved and recrystallized than gypsum. The halite crystals in the Core ZK2893 were primary, because (a) the primary fluid inclusions were developed (Figure 12), suggesting the halite was not dissolved; (b) the curve of Br in the core changed with depth (Figure 13C), consistent with the Br curve of primary halite (Figure 13A) and very different with the Br curve of secondary halite (Figure 13B); and (c) the Br of basal halite was the lowest in the core, suggesting the primary halite to have been preserved.

Basal halite is defined as the first Cl mineral to be precipitated during the evaporation of seawater/lake water. During syndepositional and early diagenetic processes, Br content of basal halite is stable [69, 71], and the initial compositions of

brine are well-preserved in basal halite [60, 71]. Therefore, the Br content of basal halite can be used to reconstruct the composition and origins of paleo-water. For example, Siemann [71] used the Br content of primary basal halite to reconstruct the Br variations in seawater over the past 500 Ma.

3.3 The isotopes of sulfur, strontium, and boron

Isotopic compositions of sulfur, boron, and strontium could be more robust indicators of the origins of evaporites (marine vs. continental origins).

3.3.1 Sulfur isotope

Waters from continental sources in general have lower $\delta^{34}S$ values than those from contemporary seawater. The $^{34}S$ values of freshwater usually range from $-5$ to $5\%$, while that of recent seawater is globally uniform with value being $20 \pm 0.5\%$ [72]. Sulfate minerals (such as gypsum and anhydrite) have stable $\delta^{34}S$ values and are typically resistant to diagenetic alteration [72–74]. Factors influencing the $\delta^{34}S$ values of evaporative sulfates are marine and nonmarine contributions, reservoirs, and redox [72, 74]. For example, bacterial-facilitated sulfate reduction is preferentially enriched in lighter $^{32}S$ isotope, and therefore, the residual sulfate minerals
Isotopes Applications in Earth Sciences

3.3 The isotopes of sulfur, strontium, and boron

Isotopic compositions of sulfur, boron, and strontium could be more robust indicators of the origins of evaporites (marine vs. continental origins).

3.3.1 Sulfur isotope

Waters from continental sources in general have lower $\delta^{34}$S values than those from contemporary seawater. The $\delta^{34}$S values of freshwater usually range from $-5$ to 5%, while that of recent seawater is globally uniform with value being 20 $\pm$ 0.5% [72]. Sulfate minerals (such as gypsum and anhydrite) have stable $\delta^{34}$S values and are typically resistant to diagenetic alteration [72–74]. Factors influencing the $\delta^{34}$S values of evaporative sulfates are marine and nonmarine contributions, reservoirs, and redox [72, 74]. For example, bacterial-facilitated sulfate reduction is preferentially enriched in lighter $^{32}$S isotope, and therefore, the residual sulfate minerals (such as gypsum) will enrich heavy $^{34}$S [72, 73]. In contrast, reservoir effects can decrease $\delta^{34}$S values of the subsequently precipitated gypsum. If sulfate evaporites precipitated in a closed system, the $\delta^{34}$S values expectedly display a gradual decrease upward in a vertical stratigraphic sequence. The reservoir effect played an active role influencing the $\delta^{34}$S values of gypsum, anhydrite, and halite in the abovementioned basins (Figure 14).

The average of $\delta^{34}$S values increase from the lower to the upper member, which indicates an evaporation effect. Microbial effect on the core’s $\delta^{34}$S$_{SO_4}$ values may be insignificant. This could be understood in the following. (a) There is no relationship between sulfate concentrations and the $\delta^{34}$S$_{SO_4}$ values of halite (Figure 14). Generally, microbial sulfate reduction can result in an inverse correlation of them [78]. And (b) the $\delta^{34}$S values observed in the halite and anhydrite are very similar. Redox recycling of bacterial reduction can result in the enrichment of $\delta^{34}$S values and significant difference within evaporites [72, 73]. Therefore, $\delta^{34}$S in this study could be used to identify the origins of brine. In the Core ZK2893, all of $\delta^{34}$S values are lower than, or similar to, those of contemporary seawater (Figure 14), suggesting a possible continental origin. Both the $\delta^{34}$S and $\delta^{18}$O$_{SO_4}$ values of halite are lower than those of Middle Cretaceous seawater (Figure 14) with a short range dispersion, shorter than that between $\delta^{34}$S and SO$_4$ values (Figure 14), suggesting that paleo-lake water possible to be mixed with freshwater.

3.3.2 Strontium isotope

Strontium is a divalent alkaline earth element. Its isotope composition is almost homogeneous with modern seawater with $^{87}$Sr/$^{86}$Sr values of 0.709175–0.709235 [79, 80]. Because the Sr composition/isotope ratios for the weathering and erosion of rocks are high [81], the $^{87}$Sr/$^{86}$Sr ratios for river water evince a large range

Figure 13.
(A) Curves of Br in primary halite in KB, after Hite and Japakasetr [69]. (B) Curves of Br in secondary halite, after Hite and Japakasetr [69]. (C) Curves of Br in the Core ZK2893 in SNB, Laos [70], suggesting the halite in the core to be primary.

Figure 14.
from 0.7074 to 0.803 (Figure 15). In a continental setting, the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio for continental waters is almost always higher than that for marine waters (Figure 15). The $^{87}\text{Sr}/^{86}\text{Sr}$ values of Paleocene halite in the Qaidam Basin (a continental basin), for example, were higher than those of Paleocene seawater (Figure 9). Thus, the $^{87}\text{Sr}/^{86}\text{Sr}$ values of authigenic minerals are very variable and higher than those of seawater when the minerals are precipitated from a solution.

As no fractionation of Sr isotopes occurs during halite precipitation, the measured halite $^{87}\text{Sr}/^{86}\text{Sr}$ ratios for Core ZK2893 (ranging from 0.707443 to 0.708587) could represent those of the parent solution. $^{87}\text{Sr}/^{86}\text{Sr}$ ratios for the lower member ranged from 0.707443 to 0.708587, averaging 0.707693, while those for the middle member ranged from 0.70752 to 0.708105, averaging 0.70764. There was only one $^{87}\text{Sr}/^{86}\text{Sr}$ ratio value in the upper member, of 0.708163. In the lower member, the possible reasons for the high $^{87}\text{Sr}/^{86}\text{Sr}$ ratios in the upper part (Figure 15) are (a) the permeation of continental waters from the middle clastic unit into the halite layers and (b) an inflow of continental waters into the Sakhon Nakhon Basin during the shrinkage process of the basin. However, the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios exhibit no significant variability in the middle member [83], suggesting no, or little, penetration of continental waters into the halite layers. The $^{87}\text{Sr}/^{86}\text{Sr}$ and $1/\text{Sr}$ halite ratios in Core ZK2893 do not show a linear relation but rather a weak positive relation (Figure 15a). Some $^{87}\text{Sr}/^{86}\text{Sr}$ ratios are far higher than those of contemporary seawater, indicating the possible input of continental waters into these evaporite basins; these $^{87}\text{Sr}/^{86}\text{Sr}$ ratios in the lower member are lower than, or similar to, those of Cretaceous seawater; further, mean Middle Cretaceous $^{87}\text{Sr}/^{86}\text{Sr}$ ratios are similar to those of paleo-seawater (Figure 15b), suggesting a marine remnant origin.

3.3.3 Boron isotope

Natural boron, a highly soluble element, has two stable isotopes ($^{10}\text{B}$ and $^{11}\text{B}$) with approximate abundances of 20 and 80%, respectively. Boron isotope
Isotopes Applications in Earth Sciences

Ironically, the $^{87}$Sr/$^{86}$Sr ratio for continental waters is almost always higher than that for marine waters. The $^{87}$Sr/$^{86}$Sr values of Paleocene halite in the Qaidam Basin (a continental basin), for example, were higher than those of Paleocene seawater. Thus, the $^{87}$Sr/$^{86}$Sr values of authigenic minerals are very variable and higher than those of seawater when the minerals are precipitated from a solution. As no fractionation of Sr isotopes occurs during halite precipitation, the measured halite $^{87}$Sr/$^{86}$Sr ratios for Core ZK2893 (ranging from 0.707443 to 0.708587) could represent those of the parent solution. The $^{87}$Sr/$^{86}$Sr ratios for the lower member ranged from 0.707443 to 0.708587, averaging 0.707693, while those for the middle member ranged from 0.70752 to 0.708105, averaging 0.70764. There was only one $^{87}$Sr/$^{86}$Sr ratio value in the upper member, of 0.708163. In the lower member, the possible reasons for the high $^{87}$Sr/$^{86}$Sr ratios in the upper part are (a) the permeation of continental waters from the middle clastic unit into the halite layers and (b) an inflow of continental waters into the Sakhon Nakhon Basin during the shrinkage process of the basin. However, the $^{87}$Sr/$^{86}$Sr ratios exhibit no significant variability in the middle member, suggesting no, or little, penetration of continental waters into the halite layers. The $^{87}$Sr/$^{86}$Sr and $1/$Sr halite ratios in Core ZK2893 do not show a linear relation but rather a weak positive relation. Some $^{87}$Sr/$^{86}$Sr ratios are far higher than those of contemporary seawater, indicating the possible input of continental waters into these evaporite basins; these $^{87}$Sr/$^{86}$Sr ratios in the lower member are lower than, or similar to, those of Cretaceous seawater; further, mean Middle Cretaceous $^{87}$Sr/$^{86}$Sr ratios are similar to those of paleo-seawater.

3.3.3 Boron isotope

Natural boron, a highly soluble element, has two stable isotopes ($^{10}$B and $^{11}$B) with approximate abundances of 20 and 80%, respectively. Boron isotope fractionation is dependent upon the distribution of boron species, temperature, and pH, but pH is the key factor. Dissolved boron exists mainly in the form of B(OH)$_3$ and B(OH)$_4^-$, which are dominantly present as $^{11}$B(OH)$_3$ at low pH values and as $^{10}$B(OH)$_4^-$ at high pH values. Because pH values increased with the increasing extent of evaporation, the minerals precipitated in early stages have higher $\delta^{11}$B values than those of minerals precipitated in later stages. Generally, the sequence of $\delta^{11}$B values of different minerals is following as: carbonate > gypsum > borate > halite > sylvite. As boron was present in inclusion, the $\delta^{11}$B values of halite and sylvite are exactly representative of those for contemporary paleo-brines. Therefore, the $\delta^{11}$B values of halite and sylvite are higher than those in carbonates and borate minerals, and all of minerals have lower $\delta^{11}$B than those of brine. In the Core ZK2893, however, the $\delta^{11}$B values of halite and sylvite were lower than those of borate minerals. One possible reason is that there have different sources of brines, such as continental, marine residue and groundwater/hydrothermal brine. In the LSB, China, most of $\delta^{11}$B values of
Isotopes Applications in Earth Sciences

halite and sylvite ranged from −1.54 to 19.1%, which are lower than those in Laos (19.9–31.1‰) (Figure 16). This suggested the paleo-brines in LSB, China, are from Laos and diluted during the flow process.

Comparison of $\delta^{11}$B values between known marine minerals and unknown minerals is a useful way to distinguish marine and continental origin. In nonmarine setting, some $\delta^{11}$B values of hydrothermal fluid, saline lake water and river water, are higher than those of seawater (Figure 16), that is, lower $\delta^{11}$B values of minerals than that of seawater are not indicate continental origin. The comparison of $\delta^{11}$B between salt minerals is valid. Although the $\delta^{11}$B values of halite in Laos were lower than those of seawater, they were near to those of marine borates (Figure 16). This suggested minor or trace marine origin. The $\delta^{11}$B values of the evaporite in LSB in China are lower than, but some are near to, those of halite and sylvite in SNB, Laos, also suggesting continental origin with minor residual seawater.

In summary, halite isotopic compositions (in the form of $\delta^{34}$S-$\delta^{18}$O-SO$_4$ values, $^{87}$Sr/$^{86}$Sr and $\delta^{11}$B) appear to represent an original composition associated with brine. These isotopic proxies indicate that continental and hydrothermal origins are likely to be more important sources of evaporite deposits than marine origins for these Laotian evaporite deposits.

4. Summary

The gypsum in the Core SG-1 was deposited directly from brines and was stable after deposition. The $\delta^{18}$O and $\delta$D curves of hydrated water in gypsum record the evolution of paleo-lake in Qaidam Basin, Western Tibetan Plateau since 2.2 Ma, including the famous cold event, mid-Pleistocene event.
In high saline conditions, the clay minerals from Core SG-1 may have undergone early diagenesis. The primary illite and chlorite contents in Core SG-1 were lower than those observed, while the primary smectite and kaolinite contents were higher than those observed. After early diagenesis, there were no isotopic exchange between the interlayer water and the ambient water. The δ¹⁸O and δD values indicated the interlayer water of clay minerals to be more concentrated than those of hydrated water. The isotopic composition of the interlayer water reflects variations in the pore water/lake water or in the reacting solutions and also records changes in environment.

Using isotopic compositions of salt minerals to identify origins of brine is a complex topic. It should be careful to use sole isotope to identify the origins. For the evaporite deposits in LSB in China and NSB, in Laos, these isotopic proxies, including δ³⁴S-δ¹⁸O-SO₄, ⁸⁷Sr/⁸⁶Sr, and δ¹¹B, indicate that continental and hydrothermal origins are likely to be more important than marine origins.

Chapter 4

Mapping the Stable Isotopes to Understand the Geo-Structural Control of Groundwater Recharge and Flow Mechanisms (Case Study From the Northeastern Basin of the West Bank)

Saed Khayat, Amer Marei and Zaher Barghouthi

Abstract

Conventional stable isotopic technique was used to differentiate between the potential recharge sources and mixing and flow mechanisms in the Northeastern basin of the West Bank. The isotopic signatures from deep wells show two main fingerprints with respect to recharge sources and mechanisms. These are wells located in the upper part of the Faria fault system and along the Rujeib Moncline which are fed by triggered water in-line the fault system in the south and deep wells surrounded by the Anabta anticline to the west which are fed by the exposed Jerusalem-Hebron formations. This suggests a mixing process with freshwater sources that mainly flow to the system from southern mountains. The isotopic signatures from the shallow well in Marj Sanoor wells and Nassariyeh in the upper Faria well suggest a kind of partial recharge from the Marj Sanoor Lake leaking to the upper Faria Graben area and participating in the recharge process of these wells. The whole finding out of this project might be used for tuning and revision of the groundwater model that has been built by the Palestinian Water Authority.

Keywords: isotope hydrology, Palestine, Northeastern aquifer, recharge mechanism, groundwater salinity

1. Introduction

Providing the Palestinian people with their water needs is the main concern for the Palestinian Water Authority, Ministry of Agriculture, as well as for water service providers. During the last 20 years, the annual average water consumption from the Northeastern aquifer reached 25 MCM [1]; this is due to improvement of water infrastructure including drilling new domestic deep wells, improvement of water institutions, and increase in the public awareness.

Tapping of groundwater, using spring water, purchase of water from Mekerot Israeli Company, and collection of rainwater are the sources for domestic and agricultural water in the West Bank. In this context, groundwater is the main one which
covers about 70% of the total water supply which is about 100–145 MCM/a from the three water basins in the West Bank, namely, Eastern, Western, and Northeastern (the study area) [1]. During the last two decades, many domestic deep wells were drilled in the Mountain Aquifer in order to improve domestic water supply, where hundreds of illegal groundwater boreholes are drilled in the shallow aquifer systems mainly in Jenin and Jericho districts.

The Mountain Aquifer system with its three groundwater basins, namely, Western, Eastern, and Northeastern basins, covers most of the West Bank area (Figure 1a). The Western and Eastern basins cover the western and eastern parts of the West Bank and extend from Hebron in the south to Jerusalem and Ramallah in the north, while the Northeastern locates in the northern part of the West Bank, within the boundary of Nablus-Beit Qad syncline. About 410,000 Palestinians are living in three main districts (Nablus, Jenin, and Tubas), within the surface catchment area of this basin. These districts include large cities such as Nablus, Jenin, Tubas, and Tammon, beside many small municipalities, villages, and refugee camps [2].

Due to the fact that groundwater is the main source of water in the West Bank, management of this source is a high priority by line ministries, so solid and advance scientific knowledge is essential for sustainable management of the water resources [4]. Identification of recharge-discharge zones, groundwater flow regimes, connection between sub-basins, as well as shallow and deep aquifer systems are vectors for better management process. Applying environmental stable isotopic is a method in hydrogeology that is used to help in identification of these vectors, so we use \( O^{18} \) [SMOW]‰ and D in the Northeastern Basin (NE Basin). We also combined the isotope analysis method, with the geological and hydrogeological setting of the sub-catchment areas [5]. High attention is given to the role of the main structural features of the groundwater flow regimes.

Recharge mechanisms, flow direction, and groundwater resident time are generally quite difficult to measure directly. Measurement of recharge flow can be exacerbated by preferential flow (i.e., macropore flow) in the unsaturated zone, although preferential flow paths are of greatest concern as potential conduits for rapid contamination of aquifers. The above factors, in addition to
temporal and spatial variability, greatly complicate the estimation of basin-wide recharge rates and flow mechanisms. Estimation methods include use of water budgets, tracers, geophysics, and simulation models. Because of the inherent uncertainties in any method, it is often advisable to apply multiple techniques for any study.

Isotopes as tracer’s isotopes for mapping the groundwater recharge and flow mechanisms are important tools in groundwater research and in sustainable management of groundwater resources. Important applications in shallow and deep groundwater include estimation of groundwater recharge and evaluation of the fate of contaminants, because meaningful groundwater deviation from the local meteoric water line LMWL gives the possibility to determine the residence time of groundwater and the dissolved contaminants [6–8].

2. Hydrogeological settings in NE Basin of the West Bank

Sedimentary rocks of the Upper Cretaceous to Quaternary ages cover most of the surface areas of the West Bank. Old rock formation exposed deep eroded area at the top of the anticlines or in deep wades and along some structural features (Figure 2a). The development of the structural features took place during the Late Upper Cretaceous-Tertiary ages, where many structural features are still active. In the study area, two anticlines and one syncline in addition to the Faria Graben are main structural features. The Anabta anticline with northwest direction, parallel to the Faria anticline with northeast axis direction, borders the study area from the west and east, respectively, where the lines at the top of boths consider as surface/sub-surface water divide. Nablus-Beit Qad syncline with northeast axis direction locates between the two anticlines [9]. Due to the erosion process, the top of the anticlines is eroded, where rock formation of Cenomanian age crops out at the top of Faria and Anabta anticline, where carbonate rock of Eocene to Quaternary ages covers the central part of Nablus-Beit Qad syncline (Figure 2b).
2.1 Stratigraphy

The stratigraphy sequences of the sedimentary rocks are the following from youngest to the oldest (Figure 1b) [10]:

2.1.1 Alluvial deposits (Quaternary to recent age)

It consists of alluvial deposits, mainly sand and gravel in flat and depression areas within the syncline. Brown earth Rendzina is the dominant soil type. The alluvial deposits cover an area of about 215 km² and normally overlay the Jenin areas within the syncline. This formation overlays the Jenin subseries formation (Figure 2b).

2.1.2 Jenin subseries (Eocene age)

It consists of six members: relief limestone, nummulitic limestone, karstified limestone, limestone, and chalky limestone. The thickness of this subseries varies from one site to another depending on the location within the syncline but generally range between 100 and 300 m. The series is considered as a local shallow aquifer system that is used mostly in the agricultural sector. The majority of the springs in the NE Basin drain water from this aquifer; in addition to that, most of the groundwater boreholes (up to 350 m depth) in Jenin governorate are tapping water from this system. This rock formation covers an area of about 378 km² (Figure 2b). This formation overlays the Abu Dis formation in the central part of the syncline, where the Jerzim Group crop outs in the southern part of Nablus city.

2.1.3 Jerzim group (Maastrichtian age)

This group crops out in Jerzim Mountain 832 m above sea level within the southern part of the syncline to the south of Nablus city. It consists of chert nodules, chalk, and chalky limestone. The thickness is about 400 m. This group is considered as a local aquifer, where many springs in Nablus city drain water from this formation along the contact line between this layer and the underlying Abu Dis chalk unit.

2.1.4 Abu Dis unit (Senonian age)

It is composed of a massive thick hard chalk unit, interbedded with two bands of highly fractured cherty layers with a distance of 2–5 m between the two bands; the material of the upper part of unit I becomes soft and unclear in bedding. The unit exposes to the surface over the anticline flanks (Figure 2b) with a thickness range between 100 m at the edges and 500 m in the middle of the syncline. This unit is considered as an impermeable layer that separates the shallow Eocene aquifer from the underlying Jerusalem formation that is considered as the upper part of the Upper Mountain Aquifer system. The chalky units cover an area of about 153 km².

2.1.5 Jerusalem formation (Turonian age)

This formation consists of thin-bedded highly fractured limestone and dolomitic limestone. The lower part consists mainly of rosy limestone, where oyster fossil could be found at the top of this formation with variable thickness range between 70 and 150 m thick. This formation is cropped out mainly over the anticline and considered as recharge zone, where below the central part of the syncline consider as good aquifer. This formation overlaps the Bethlehem formation (Figure 2b, Upper Aquifer).
2.1.1 Alluvial deposits (Quaternary to recent age)

Alluvial deposits cover an area of about 215 km² and normally overlay the Jenin areas within the syncline. Brown earth Rendzina is the dominant soil type.

2.1.1.10 Lower Bet Kahel Formation (Albian)

It consists of gray limestone layers alternating with layers of shale and marl in the lower part, whereas the upper part is made up of gray to brown dolomite with clayey and marly limestone.

Both formations are considered as Lower Aquifer system of the Mountain Aquifer in the southern part of the West Bank, but in the northern part of the Upper and Lower Aquifer system, they are considered as one hydrological system. The outcrop area of the deep aquifer system is about 33 km². The two formations crop out also in deep eroded streams within the Faria anticline as well as within the Faria Graben.

2.2 Hydrology

Rainy months extend from October to May, where 70% of the rainfall takes place between December and February. Figure 3 shows the rain fall distribution during...
the hydrological year 2015/2016, where three high rainfall zones are identified namely within the boundary of the basin, these are north of Nablus, Selet al Thaher with 600 and 800 mm/a respectively [11]. It’s also noticed that rainfall decreases in the eastward direction of the Faria Graben which locates more within the rainfall shadow site (Figure 3). The average monthly temperature during December, January, and February is 11, 14, 17°C. respectively; this indicate that the losses of water through evapotranspiration is relatively low during these months which improve the groundwater recharge rate [12].

2.3 Groundwater aquifer systems

The Northeastern Basin covers 959 km² of surface area (Figure 1b), depending on surface water shed divide; within the basin, two aquifer systems are identified; Mountain Aquifer with rock layers related to the Upper Cretaceous age, and shallow aquifer with rock layers related to the Tertiary-Quaternary eras (Eocene-Miocene age). Both systems are hydraulically separated from each other in most of the basin especially in the central part but seems to be connected where deep structural features strike the rock layers of both systems, such as in Al Faria Graben [13].

Recharge process for both aquifer systems takes place wherever the rock formation is outcropped and exposed directly to the rainfall or underlying thin soil layers. Marei et al. estimate the groundwater recharge rate, by using chloride mass balance method for the study area, of about 95.2 and 269.7 mm/year, with a total average recharge volume of 138.5 MCM/year (Figure 4) [14], while the total calculated recharge rate by the previous study of the authors is 107.1 MCM/a [14]. Recharge rate can be higher than estimated when karstic and high fractured rock layers are cropped out at the surface such as the formation of the Upper and Lower Mountain aquifer system at the two anticline flanks in the west and in the east, in the other hand ground recharge decrease to about zero from Abu Dis formation “Chalky Unit”. The formation of shallow aquifer system is exposed mainly in the central part of the basin, and water body responds quickly to rainfall.
In the hydrological year 2015/2016, three high rainfall zones are identified within the boundary of the basin, namely north of Nablus, Selet al Thaher with 600 and 800 mm/a respectively [11]. It's also noticed that rainfall decreases in the eastward direction of the Faria Graben which locates more within the rainfall shadow site (Figure 3). The average monthly temperature during December, January, and February is 11, 14, 17°C respectively; this indicates that the losses of water through evapotranspiration is relatively low during these months which improve the groundwater recharge rate [12].

2.3 Groundwater aquifer systems

The Northeastern Basin covers 959 km² of surface area (Figure 1b), depending on surface water shed divide; within the basin, two aquifer systems are identified; Mountain Aquifer with rock layers related to the Upper Cretaceous age, and shallow aquifer with rock layers related to the Tertiary-Quaternary eras (Eocene-Miocene age). Both systems are hydraulically separated from each other in most of the basin especially in the central part but seems to be connected where deep structural features strike the rock layers of both systems, such as in Al Faria Graben [13].

Recharge process for both aquifer systems takes place wherever the rock formation is outcropped and exposed directly to the rainfall or underlying thin soil layers. Marei et al. estimate the groundwater recharge rate, by using chloride mass balance method for the study area, of about 95.2 and 269.7 mm/year, with a total average recharge volume of 138.5 MCM/year (Figure 4) [14], while the total calculated recharge rate by the previous study of the authors is 107.1 MCM/a [14]. Recharge rate can be higher than estimated when karstic and high fractured rock layers are cropped out at the surface such as the formation of the Upper and Lower Mountain aquifer system at the two anticline flanks in the west and in the eastern hand, ground recharge decrease to about zero from Abu Dis formation “Chalky Unit”. The formation of shallow aquifer system is exposed mainly in the central part of the basin, and water body responds quickly to rainfall.

Table 1. Recharge volume of NE Basin.

Table 1 summarized the recharge volume of the deep and shallow aquifer systems depending on the chloride mass balance method [14].

2.4 Groundwater flow regimes

Two main groundwater flow regimes are assumed to present in the study area. These are as follows: a SW-NE main groundwater flow direction parallel to
Nablus-Beit Qad syncline axis with historical discharge site in Hiteen and Ein Jaloot spring and a flow direction from both anticline flanks (Anabtaa, and Al Faria) to the center of the syncline which joins the NE flow direction; these flow directions take place within the Mountain Aquifer system [15, 16]. Addition flow direction to the southeast is governed through Al Faria fault system “Graben” that diverted groundwater to flow in this direction [17].

3. Methodology

Integrated isotopic tools were used to investigate the effect of complex geologic structure on the groundwater residence times and respective potential sources, mixing, and recharge mechanisms [18]. In order to achieve the abovementioned objectives, 82 groundwater samples were obtained from different areas in the Northeastern basins. The samples represent 8 springs, 20 wells from shallow Eocene aquifer in the plain zone of the study area, 7 wells in Sanoor swamp area, 10 shallow wells in Nassariyeh area in the upper part of Wadi Faria stream, 20 wells from the lower part of Faria stream, and 17 deep aquifer wells within and near the flanks of the NE basin (Figure 5). All samples were taken in the hydrological year 2017/2018. Several rainwater samples were obtained from rain gauges’ stations that were constructed on the roofs of some schools all over the study area.

Groundwater samples for deuterium and δ¹⁸O isotopes have been taken from the mentioned wells and spring. Samples for deuterium and δ¹⁸O isotopes were collected with 25 ml bottles and sent to the Al-Quds University research lab for analysis. Samples were analyzed using laser spectroscopy for deuterium and δ¹⁸O in ‰ in respect to Vienna Standard Mean Ocean Water (V-SMOW) standard; the precision of δ¹⁸O[SMOW] ‰ measurements is ±0.1‰; the precision of δD values is ±2‰ [19].

4. Results and discussion

4.1 Results overview

The local meteoric water line shows the same slope for the Mediterranean Meteoric Water Line but with more enriched deuterium excess. This might refer to the formation of a large swamp lake in Sanoor area which resulted from the inundation from the runoff drained to the area from the surrounded mountains causing high humid conditions in the area (Figure 6).

The data show a wide range of isotopic signatures, which reflects wide variations with respect to recharge mechanisms and groundwater flow directions. Figure 5 shows the distribution of sampled wells and different geological structures that control the hydrology of the region. As it is mentioned above, the structural geology is highly controlling the hydrological flow system in the region. The main structure that might play an important role in this regard is the Faria fault system which might control the groundwater flow regime in the eastern part of the NE Basin.

Spring systems in both locations (Bathan in the east and Nablus in the northwest) show closed signatures to the local meteorological line, which indicate rapid freshwater input; the other end member of shallow wells within the middle of the syncline shows the most enriched signatures (Figure 6).

Other wells, which show signatures in between, have different recharge mechanisms which need to be separated in details with respect to isotopic signature from each group.

The following sections illustrate the relations between different aquifers as well as the recharge mechanism for each system.

4.2 Deep wells

The isotopic signatures from deep wells show two main fingerprints with respect to recharge sources and mechanisms.

First, the deep wells that are located within the area of the Faria fault system, southern part of the syncline and upper part of Faria fault system, show depleted signatures that are more or less closed to springs and LMWL, while other deep wells reflect high variation in isotopic enrichment with respect to its depth and location.

Figure 6. Deuterium vs. $\delta^{18}O_{(SMOW)}$ ‰ for the whole wells and springs in the study area.
Some of the deep wells show obvious close relation to the recharge that feeds the aquifer layers through the exposed Jerusalem-Hebron formations on Anabta anticline (Figure 7), where the wells within this area show more enriched $\delta^{18}O$ signatures than those near the upper Faria fault system (Figure 7).

The isotopic signatures of deuterium show clear differences between each deep well cluster with an average shifting of 4‰. These differences are more or less related to the recharge locations with different altitudes [20].

The deep wells in the south and upper part of Faria show relatively more depleted deuterium than those deep wells that receive direct recharge from the western Anabta anticline outcrops. The elevation of Anabta anticline in the western part of the basin has an average altitude of 300 m above sea level, while the southern elevation over the mountains in Nablus and Salfit areas to the south, from where the recharge for deep Faria well cluster is expected, reaches an average of 500 m above sea level.

However, the $\delta^{18}O$ signatures show slight shifting between both clusters, with more slight enrichment for the wells near to the western Anabta anticline that reach around −1‰. This also reflect different recharge mechanisms and different hydrological flow conditions from each source [21].

Figure 8 shows the suggested recharge zones and flow mechanisms for each of deep well cluster.

4.3 Shallow wells

This group of wells can be divided into three major categories according to its locations: shallow Eocene wells that are distributed in the plain area of syncline, Sanoor wells which are belonging to the same previous area but located directly within the area of surface water swamp, and upper Faria (Bathan) shallow wells in Nassariyeh area and lower Faria shallow wells to the southeast.
Isotopes Applications in Earth Sciences

Some of the deep wells show obvious close relation to the recharge that feeds the aquifer layers through the exposed Jerusalem-Hebron formations on Anabta anticline (Figure 7), where the wells within this area show more enriched $\delta^{18}O$ signatures than those near the upper Faria fault system (Figure 7). The isotopic signatures of deuterium show clear differences between each deep well cluster with an average shifting of 4‰. These differences are more or less related to the recharge locations with different altitudes [20].

The deep wells in the south and upper part of Faria show relatively more depleted deuterium than those deep wells that receive direct recharge from the western Anabta anticline outcrops. The elevation of Anabta anticline in the western part of the basin has an average altitude of 300 m above sea level, while the southern elevation over the mountains in Nablus and Salfit areas to the south, from where the recharge for deep Faria well cluster is expected, reaches an average of 500 m above sea level.

However, the $\delta^{18}O_{[SMOW]}$ ‰ signatures show slight shifting between both clusters, with more slight enrichment for the wells near to the western Anabta anticline that reach around $-1‰$. This also reflects different recharge mechanisms and different hydrological flow conditions from each source [21].

Figure 8 shows the suggested recharge zones and flow mechanisms for each of deep well cluster.

4.3 Shallow wells

This group of wells can be divided into three major categories according to its locations: shallow Eocene wells that are distributed in the plain area of syncline, Sanoor wells which are belonging to the same previous area but located directly within the area of surface water swamp, and upper Faria (Bathan) shallow wells in Nassariyeh area and lower Faria shallow wells to the southeast.

According to isotopic signatures from these shallow wells, different recharge mechanisms for each group can be indicated. Also the isotope data reflect some hydrological connections between some groups. The hydrological relations as well as recharge mechanisms can be described with respect to each group.

4.3.1 Shallow wells within the Eocene plain area

This includes the shallow wells that are dug in the Eocene and Quaternary alluvial areas in the northwest of Nablus-Bet Qad syncline (Figure 5). Those wells show high evaporation inputs with relatively high TDS content. The $\delta^{18}O_{[SMOW]}$ ‰ and deuterium values for the shallow wells in the Al Jalameh (north) indicate relatively enrichment deviation from the LMWL due to fractionation with the thick soil layer during slow infiltration. For these wells, the $\delta^{18}O_{[SMOW]}$ ‰ values reach $-3.5‰$ (Figure 6). The deviation from LMWL with the slope of 4 indicates an evaporation trend that increases toward the north of the study area where those wells tapped their water from (Figure 6).

In general, the problem of water deterioration in this group seems to be connected with the heavy abstraction rate from these wells. The slow replenishment, with such heavy abstraction, increases the evaporite salinity problem [22].

In general, Marj Sanoor wells show relatively enriched $\delta^{18}O$ signatures but less than the rest of shallow wells in the north (Figure 6). This might be due to the fact that the aquifer is located beneath the water swamp that is collected in the winter time and infiltrated slowly to the aquifer layers. The integration of the results with the results of other locations shows a connection between the infiltrated surface water from this group with some wells to the southeast as it will be described below.

4.3.2 Shallow wells in Nassariyeh

The shallow wells in Nassariyeh that are located at the beginning of Faria structural faults show the same stable isotopic signatures as Marj Sanoor wells. This
strongly suggests a connection between seeping water from the seasonal Marj Sanoor Lake, which forms by the collected runoff from surrounding mountains in the late winter season to the wells that are located within the upper Faria and Bathan area (Figure 9).

The isotopes signatures suggest that the recharge mechanism for these wells is a mixing between water seepage from Marj Sanoor surface water and fresh water that
Figure 10. Suggested groundwater model for the water leakage from Marj Sanoor Lake to the Nassaria and upper Faria wells. Strongly suggests a connection between seeping water from the seasonal Marj Sanoor Lake, which forms by the collected runoff from surrounding mountains in the late winter season to the wells that are located within the upper Faria and Bathan area (Figure 9). The isotopes signatures suggest that the recharge mechanism for these wells is a mixing between water seepage from Marj Sanoor surface water and fresh water that line the Faria Fault that triggered from deeper Jerusalem formation, and seeping along the area of Faria Graben (Figure 10).

This finding can be used to efficiently utilize the surface water in the syncline area to artificially feed the wells further to the east, keeping the groundwater level in good standing all over the summer season. On the other hand, heavy abstraction from the shallow and deep wells within the syncline area might affect the productivity of Bathan and upper Faria wells.

Figure 11. Relation between $\delta^{18}O_{\text{SMOW}}$‰ and deuterium for the groundwater from deep wells and lower Faria shallow wells.

Figure 12. Model of groundwater recharge and flow mechanisms for the lower Faria wells from different sources.
4.3.3 Lower Faria shallow wells

The isotopic signatures from lower Faria shallow wells suggest strong correlation with the recharge of the deep well in the upper Faria part. Most of the shallow lower Faria wells show the same $\delta^{18}$O and deuterium signatures for the deep wells of Bathan, Faria, Tubas, and Tammoun. This similarity emphasizes the unity of recharge mechanism for both locations which mainly come from Jerusalem formation of Turonian age, that triggered along the northern Faria fault and seeping to the wells drilled within lower Faria plain (Figures 11 and 12).

However, the isotopic signatures show enrichment trend with respect to distance from the fault to the middle and the south of the Wadi (Figure 13). This emphasizes that the main recharge source for the wells in the lower Faria is coming mainly from the northwest, in-line the Fault system (Figure 12).

This also can be an indicator about the limitation of the water recharge from the southern part of the Fault, which suggests in role that most of the recharge in the southern area is drain surfacely and sub-surfacely to the area constrains between the southern Faria Fault and Bet Forik Fault, where the mentioned area must be a good potential for freshwater production with sufficiently high amount.

5. Conclusion and recommendations

The isotopic signatures from deep wells show two main fingerprints with respect to recharge sources and mechanisms. Those are wells located in the upper part of Faria fault system and along the Rujeib Moncline which are fed by triggered water in-line the Fault system in the south and deep wells surrounded by Anabta anticline to the West which are fed by the exposed Jerusalem-Hebron formations. This suggests a mixing process with freshwater sources that mainly flow to the system from southern mountains. However, the impermeability of the southern part of Faria fault system makes this water diverted to the area constrain between the southern
Faria fault and Bet Forik faults, where the mentioned area must be a good potential for freshwater production with sufficiently high amount (Figure 13).

The isotopic signatures from the shallow well in Marj Sanoor wells and Nassariyeh in the upper Faria well suggest a kind of partial recharge from the Marj Sanoor Lake that leaks to the upper Faria Graben area and participates in the recharge process of these wells. This finding can be used to efficiently utilize the surface water in the syncline area to artificially feed the wells further to the east, keeping the groundwater level in good standing all over the summer season. On the other hand, heavy abstraction from the shallow and deep wells within the syncline area might affect the productivity of Bathan and upper Faria wells.

The northern part of the Faria Graben fault which shows a good ability for freshwater transmission from different sources is extended further to the north-west, reaching the syncline area. The area of fault extension can be a good potential source for drilling new wells in the future.

The whole finding of this project might be used for tuning and revision of the groundwater model that has been built by the Palestinian Water Authority. The suggested new flow mechanisms and potential recharge zones can help the Palestinian stakeholders in good planning for the whole Northeastern aquifer system.

Chapter 5
Could Coral Skeleton Oxygen Isotopic Fractionation be Controlled by Biology?
Anne Juillet-Leclerc

Abstract
During 1970s, coral skeleton oxygen isotope composition ($\delta^{18}O$) was regarded as the isotopic thermometer following thermodynamic rules. Recently, coral aragonite oxygen isotopic fractionation could appear to be controlled by biology, its rate being accelerated by an enzyme (carbonic anhydrase or CA). Such a new concept results of an original approach involving coral culture in controlled conditions. Environmental factors, temperature and also light have been tested on macrosize scale samples (some mg), and $\delta^{18}O$ revealed vital effects, anomalies compared with chemical and isotopic equilibrium, related to metabolic activity. $\delta^{18}O$ analyses at microsize scale (some $\mu$m), using ion microprobe, could display the mechanism of crystallisation, $\delta^{18}O$ fractionation responding to biological kinetic effects. The understanding of coral aragonite $\delta^{18}O$ is the absolute prerequisite to develop the first model of a coral proxy.

Keywords: oxygen isotopic fractionation, coral skeleton, culture, controlled conditions, temperature, light, organic matrix

1. Introduction
Coral colonies built the most important bioconstruction made of calcium carbonate (CaCO$_3$) of the world, with a calcification of about 2–6 kgCaCO$_3$ m$^{-2}$ year$^{-1}$ covering an area of about 284,300 km$^2$ [1]. This construction built from Jurassic results from the work of multiple small colonial organisms. The reefs, the biotic mound structure essentially made of corals as the Great Barrier Reef in Australia, are of major importance for marine ecosystems and biodiversity because they are the most productive and they host almost a third of all world fishes.

Corals are marine animals forming an aragonite (a polymorph of CaCO$_3$) skeleton. They are developed in two distinct ecosystems, essentially zooxanthellate corals or symbiotic ones living in shallow water and solitary colonies or integrated in elaborate reef framework in deeper depth than 50 until 2000 m. More than 793 coral species are spread over marine tropical zone [2]. Branched corals Acropora and massive corals Porites are ubiquitous genera [3]. We restricted this study to zooxanthellate corals.

Epstein [4, 5] demonstrated that skeletal carbonates of marine shells display similar oxygen isotopic composition ($\delta^{18}OCaCO_3$) relationship versus SST than inorganic calcium carbonate (CaCO$_3$) deposited from seawater at the same temperature, following thermodynamic laws.
Chapter 5

Could Coral Skeleton Oxygen Isotopic Fractionation be Controlled by Biology?

Anne Juillet-Leclerc

Abstract

During 1970s, coral skeleton oxygen isotope composition ($\delta^{18}$O) was regarded as the isotopic thermometer following thermodynamic rules. Recently, coral aragonite oxygen isotopic fractionation could appear to be controlled by biology, its rate being accelerated by an enzyme (carbonic anhydrase or CA). Such a new concept results of an original approach involving coral culture in controlled conditions. Environmental factors, temperature and also light have been tested on macroscale samples (some mg), and $\delta^{18}$O revealed vital effects, anomalies compared with chemical and isotopic equilibrium, related to metabolic activity. $\delta^{18}$O analyses at microscale (some $\mu$m), using ion microprobe, could display the mechanism of crystallisation, $\delta^{18}$O fractionation responding to biological kinetic effects. The understanding of coral aragonite $\delta^{18}$O is the absolute prerequisite to develop the first model of a coral proxy.

Keywords: oxygen isotopic fractionation, coral skeleton, culture, controlled conditions, temperature, light, organic matrix

1. Introduction

Coral colonies built the most important bioconstruction made of calcium carbonate (CaCO$_3$) of the world, with a calcification of about 2–6 kg$_{CaCO_3}$ m$^{-2}$ year$^{-1}$ covering an area of about 284,300 km$^2$ [1]. This construction built from Jurassic results from the work of multiple small colonial organisms. The reefs, the biotic mound structure essentially made of corals as the Great Barrier Reef in Australia, are of major importance for marine ecosystems and biodiversity because they are the most productive and they host almost a third of all world fishes.

Corals are marine animals forming an aragonite (a polymorph of CaCO$_3$) skeleton. They are developed in two distinct ecosystems, essentially zooxanthellate corals or symbiotic ones living in shallow water and solitary colonies or integrated in elaborate reef framework in deeper depth than 50 until 2000 m. More than 793 coral species are spread over marine tropical zone [2]. Branched corals Acropora and massive corals Porites are ubiquitous genera [3]. We restricted this study to zooxanthellate corals.

Epstein [4, 5] demonstrated that skeletal carbonates of marine shells display similar oxygen isotopic composition ($\delta^{18}$O$_{CaCO_3}$) relationship versus SST than inorganic calcium carbonate (CaCO$_3$) deposited from seawater at the same temperature, following thermodynamic laws.
δ^{18}O = \left\{ \left[ \frac{(^{18}O / ^{16}O)}{\text{sample}} / \left( \frac{^{18}O / ^{16}O}{\text{standard}} \right) - 1 \right] \right\} \times 10^{-3}

The relationship was expressed as:

SST°C = 16.5 – 4.3 \left( \delta^{18}O_{\text{CaCO}_3} - \delta^{18}O_{\text{seawater}} \right) + 0.14 \left( \delta^{18}O_{\text{CaCO}_3} - \delta^{18}O_{\text{seawater}} \right)^2 \quad (1)

from [5] with sea surface temperature (SST) being sea surface temperature and \( \delta^{18}O_{\text{seawater}} \) seawater isotopic composition. The authors underlined that coral skeleton presented poor interest [4].

However, after preliminary studies [6], Weber and Woodhead deduced, despite apparent isotopic disequilibrium between coral skeletal carbonate and ambient seawater, that \( \delta^{18}O_{\text{coral}} \) was temperature dependent. To support this assumption [2], the authors conducted isotopic analyses of coral skeleton collected over wide range of temperatures. This data series still constitutes the most exhaustive oxygen isotopic database existing for corals. Weber and Woodhead concluded that the calibration between annual \( \delta^{18}O \) and annual SST differed following each coral genus, and the isotopic disequilibrium was attributed to vital effect, anomalies compared with chemical and isotopic equilibrium, related to metabolic activity. Several models of mineralisation were proposed to explain the geochemical specificities of coral skeletons based on kinetic fractionation [7–9] disturbed by “vital effects”. Other models, based on precipitation efficiency [10] or Rayleigh fractionation [11–13], were suggested.

We developed drastically different approach considering that corals are animals living in symbiosis with algae, building aragonitic skeleton intimately related to biological activity. In collaboration with biologists from CSM (Centre Scientifique de Monaco), Stéphanie Reynaud and Christine Ferrier-Pagès, and Claire Rollion-Bard geochemist from IPGP (Institut Physique du Globe de Paris), we developed an innovative strategy on cultured Acropora to identify what was hidden under the term of vital effect of coral skeleton and to highlight the isotopic fractionation involved in. We focused our study on the stable oxygen isotopic ratio \( \delta^{18}O \). Branched coral Acropora and massive ones Porites belong to different genera but responses to environmental forcing in terms of biological parameters and isotopic signatures are regarded as similar.

Our demonstration is structured as followed: first, the main coral features are highlighted; second, we describe coral culture proceeding; third, temperature and light test results are presented at microscopic size scale; and finally, we display the stable oxygen isotopic ratio \( \delta^{18}O \) as indicator of deposit mechanism.

2. Main coral features

Shallow corals, because they are leaving in symbiosis with micro algae need light to benefit from photosynthetic activity.

2.1 Notions of coral morphology and biological activity

Coral skeleton is extracellular, located at the base of coral tissue, constituted of similar units, the polyps. Each polyp looks like a bag made by two layers of cells (Figure 1). Polyps are linked together by the coenosarc. Most of zooxanthellae are located within an internal layer (Figure 1).

Biological activity might be quantified. Photosynthesis and respiration were measured using the respirometry technique, which measured the changes in oxygen concentration at different light levels. Rates of net photosynthesis and respiration

\[ \text{Rate of net photosynthesis} = \frac{\Delta [O_2]}{\text{time}} \]

\[ \text{Rate of respiration} = \frac{\Delta [O_2]}{\text{time}} \]
Could Coral Skeleton Oxygen Isotopic Fractionation be Controlled by Biology?

Figure 1. Organisation of the coral adapted from [14]. The colour polyp is the living organism, an animal building the white skeleton. The animal lives in symbiosis with algae, the zooxanthellae, located in the internal layer (the left side high corner). A detail of mesoscale skeletal architecture figures on the left side bottom corner.

were estimated using a linear regression of $O_2$ against time [15]. By using two light intensities, at three temperatures (Figure 2), it appeared that increasing temperature enhanced photosynthetic activity, the effect arising with light intensity (Figure 2a) [15]. Additionally, coral growth rates might be estimated. Corals were weighed regularly using the buoyant weight technique and the surface expansion of the new skeleton formed was estimated [15]. It was generally accepted that calcification was light-enhanced (LEC or light enhanced calcification) during the day [16]. Zooxanthellae density and pigment concentration were determined under the light microscope using a counting chamber [15]. Coral symbiont distribution was not homogeneous on the skeleton and it differed following different coral genera, different depths in the fields. For example, tips of coral branches or other exposed surfaces were sun-adapted while most of the lowest parts were shade-adapted [15]. Iluz and Dubinsky [17] listed all the strategies developed by coral to optimise the light impinging on the zooxanthellae.
2.2 Microstructures of coral skeletal

It was admitted that the coral skeleton such as coral *Acropora* (Figure 3a and b) or coral *Porites* presented composite mineral microstructures: centres of calcification (COC) and fibres, embedded in a few organic matter as a network [18]. COC were massive randomly oriented crystals called fusiform crystals (Figure 3c, h and i) [19], and numerous needle-like crystals projecting in many directions from the fusiform crystals were called the fibres gathered into bundles (Figure 3f) [19] oriented perpendicularly to the growth axis (Figure 3e) [19].

Skeletogenesis could be the result of two different processes: the deposition of fusiform crystals and the progressive thickening of the initial framework by needle like crystals (Figure 3f) [19].

These crystalline elements were differently distributed according to morphology [19–21]. Each microstructure is preferentially present in some morphological parts, which were more or less developed following the genus [22]. However, we know that they are composed by identical microstructures and only differ by their relative amounts.

Biologic response of net productivity (a), zooxanthellae density according to net productivity (b) and averaged δ¹⁸O-temperature calibration under high light (HL) and low light (LL) (c).
2.2 Microstructures of coral skeletal

It was admitted that the coral skeleton such as coral *Acropora* (Figure 3a and b) or coral *Porites* presented composite mineral microstructures: centres of calcification (COC) and fibres, embedded in a few organic matter as a network [18]. COC were massive randomly oriented crystals called fusiform crystals (Figure 3c, h and i) [19], and numerous needle-like crystals projecting in many directions from the fusiform crystals were called the fibres gathered into bundles (Figure 3e, f and g) [19] oriented perpendicularly to the growth axis (Figure 3e) [19].

Skeletogenesis could be the result of two different processes: the deposition of fusiform crystals and the progressive thickening of the initial framework by needle-like crystals (Figure 3f) [19].

These crystalline elements were differently distributed according to morphology [19–21]. Each microstructure is preferentially present in some morphological parts, which were more or less developed following the genus [22]. However, we know that they are composed by identical microstructures and only differ by their relative amounts.

Figure 2. Test using a factorial design of three temperatures (22, 25, and 28°C) and two light intensities (200 and 400 μmol photon m−2 s−1) of cultured *Acropora*. Biologic response of net productivity (a), zooxanthellae density according to net productivity (b) and averaged δ18O-temperature calibration under high light (HL) and low light (LL) (c).
δ¹⁸O differed following microstructures at microscopic size scale (Figure 3j and k) [27]. This was confirmed later on [28, 29]. COC δ¹⁸O was lower, while fibre δ¹⁸O was higher and variable between equilibrium and COC value (Figure 3j and k) [29].

3. Calibrations of annual and monthly δ¹⁸O-temperature

3.1 Weber and Woodhead (1972) data set and annual calibrations revisited

Weber and Woodhead [3] established a formula able to predict past SST following the isotopic thermometer concept [30], expressed as:

$$\text{SST}° \text{C} = a \times \delta^{18}\text{O} (\%e) + b$$

(2)

(a) and (b) being constants (instead of A and B in [3]). Because Acropora and Porites are ubiquitous genera, Acropora and Porites δ¹⁸O calibration deriving from 835 and 421 sample, respectively, calibrations (Figure 4a and b) might be regarded as statistically significant. Moreover, isotopic analyses were conducted on annual samples, identified by X-ray growth bands, a pair of clear and dark bands corresponding to the annual growth [31]. Each temperature

Annual δ¹⁸O of several coral genera derived from [3]

![Annual δ¹⁸O of several coral genera derived from [3]](image)

Figure 4. Annual coral δ¹⁸O measures performed on several genera from revisited dataset of [3] (a–e). Location of the 29 sites where coral samples were collected, prescribing temperature values (a). Calibrations of 44 coral genera following δ¹⁸O(‰) = a × SST°C + B (b). The colours highlight genera sharing identical temperature and isotopic ranges, underlining the convergence of the groups including Acropora and Porites. Calibrations of some coral genera Acropora, Porites, Platygira, Montipora or Pavona following δ¹⁸O_carbonate = a × δ¹⁸O(‰) + b (c). The colours of the calibrations correspond with colours from (c), strongly significant linear relationship linking constants a and b, of annual δ¹⁸O-annual temperature calibrations for 44 coral genera (d). Strongly significant linear relationship linking constant of annual δ¹⁸O-annual temperature calibrations for groups highlighted on (c and e).
value, corresponding to one island, as associated to the averaged δ\(^{18}\)O measured for corals of the same species, all receiving identical local irradiation. Groups of genera including *Acropora* or *Porites* displayed strong convergence.

The dataset [3] did not take into account δ\(^{18}\)O\textsubscript{seawater}. Juillet-Leclerc and Schmidt [32] included annual δ\(^{18}\)O\textsubscript{seawater} values assessed in the calibration established for *Porites* following the formula:

\[
\delta^{18}O\text{carbonate} - \delta^{18}O\text{seawater} = -0.20 \times \text{SST (°C)} + 0.45 \quad (3)
\]

with \(R^2 = 0.83\), \(N = 22\), \(p < 0.001\), only significant over the SST range from 24 to 30°C [32].

However, the correlation linking δ\(^{18}\)O directly to temperature showed a higher coefficient [3]:

\[
\delta^{18}O\text{carbonate} = -0.27 \times \text{SST (°C)} + 2.24 \quad (4)
\]

with \(R^2 = 0.91\), \(N = 24\), \(p < 0.001\) including the lowest temperatures neglected in Eq. (5) [32].

A similar procedure was conducted for *Acropora*, using the same δ\(^{18}\)O\textsubscript{seawater}. We obtained:

\[
\delta^{19}O\text{carbonate} - \delta^{18}O\text{seawater} = -0.21 \times \text{SST (°C)} + 1.26 \quad (5)
\]

with \(R^2 = 0.87\), \(N = 24\), \(p < 0.001\), significant over the temperature range from 21 to 30°C (*Figure 4e*).

the correlation linking δ\(^{18}\)O directly to temperature showed a higher coefficient [3]:

\[
\delta^{18}O\text{carbonate} = -0.28 \times \text{SST (°C)} + 3.34 \quad (6)
\]

with \(R^2 = 0.98\), \(N = 27\), \(p < 0.001\), significant over the temperature range from 21 to 30°C.

Slopes (a) shown by *Porites* and *Acropora* temperature calibrations including δ\(^{18}\)O\textsubscript{seawater} \(-0.20\) and \(-0.21\)%/°C, respectively, differed from those deriving only from δ\(^{18}\)O\textsubscript{carbonate} (referred as δ\(^{18}\)O in the following) and temperature. They were close to the slope of \(-0.19\)%/°C assessed for inorganic aragonite calibration [33]. Slopes have been also obtained from other genera such as *Platygira*, *Montipora* or *Pavona* (*Figure 4e*) [3].

After introducing δ\(^{18}\)O\textsubscript{seawater} into dataset [3], for *Porites* and *Acropora* genera, the usual therodynamic equation is significant but to a lower degree, compared to Eqs. (4) and (6). For example, by taking into account only temperature, \(R^2 = 0.91\) and 0.98 instead of 0.87 and 0.93 for *Porites* and *Acropora* respectively.

In the calibrations depending only on temperature, temperature might act first, according to thermodynamic law [5, 15] and second, through the photosynthetic process [34] (*Figure 2a*), which was enhanced by a temperature increase. Therefore, an increase in temperature induced a decrease in δ\(^{18}\)O following the first process while the second mechanism caused a rise in δ\(^{18}\)O, confusing the global isotopic effect. Temperature influences δ\(^{18}\)O twice, explaining that temperature is the main factor, which does not exclude the role of δ\(^{18}\)O\textsubscript{seawater}.

Calibrations taking into account δ\(^{18}\)O\textsubscript{seawater} exhibited a slope value close to isotopic equilibrium of inorganic aragonite with water, suggesting that under quasi-uniform light, the isotopic offset of coral δ\(^{18}\)O is constant, regardless of temperature (*Figure 4c*). Eqs. (3) and (4) confirm that, to a lesser degree than temperature, δ\(^{18}\)O\textsubscript{seawater} may be included in a calibration.
When comparing constants (a) and (b) of Eq. (2) from data series [3], for all genera annual $\delta^{18}$O-annual temperature calibrations (Figure 4d), we obtained a strongly significant linear relationship:

$$b = -29.07 \times a - 5.13$$ (7)

with $R^2 = 0.95$, $N = 37$ and $p < 0.001$. (a) corresponds to a disequilibrium indicator compared to $-0.19$, the slope value derived from the theoretical $\delta^{18}$O at equilibrium [34]. Such a relationship was not hazardous, but reflected inherent features of annual $\delta^{18}$O-annual SST calibrations. Linear calibrations determined from single genus deduced from figures or table of [3], showed strong correlation coefficients: $R^2 = 0.99$ (Figure 4e).

This suggests that the $\delta^{18}$O SST dependence is based on a unique rationale according to taxonomy, in turn inherent to the coral skeleton.

Dataset [3] revealed unique relationship between annual $\delta^{18}$O-annual temperature calibrations of each genus, because coral taxonomy is based on morphology. Land et al. [22] stressed the high $\delta^{18}$O variability following the longitudinal section on the calices of some species or the septa dentations of another one, inducing that according to coral morphology, some skeleton portions might be more or less developed, implying a large isotopic variability.

We underlined the relationship existing between the annual $\delta^{18}$O-annual SST calibration constants. However, identical feature was highlighted for annual Sr/Ca-annual temperature calibrations [35–37]. The link existing between $\delta^{18}$O and Sr/Ca is not straightforward, oxygen being a component of CaCO3 and Sr/Ca an impurity included in the skeleton. However, it is possible to recognise common $\delta^{18}$O and Sr/Ca behaviour relative to their microstructure distribution in the coral and the concept of taxonomy.

Coral skeleton presents composite mineral microstructures: centres of calcification (COC) and fibres, embedded in a few organic matter as a network [18], differently distributed according to morphology [19–21]. Latter authors show that COC and fibres are essentially present in morphological parts, more or less developed following the genus. On the one hand, $\delta^{18}$O signature differs according to the microstructures [19–21], COC $\delta^{18}$O being lower than fibre $\delta^{18}$O [29] (Figure 3j and k). On the other hand, Sr/Ca ratios measured on COCs are higher than those of fibres [9]. Cohen et al. [37] examined synchronously deposited microstructures on Porites lutea over a year, exhibiting COC elemental ratios systematically higher compared to those of fibres developed over an identical period. Thus, it is the proof that annual COC Sr/Ca value is higher than the annual fibre Sr/Ca signature [37]. Therefore, we suggested that discrepancies of morphology existing between coral genera are due to differences of microstructure proportions [22], explaining common features between the annual trace element ratio- and annual $\delta^{18}$O-annual temperature calibrations.

### 3.2 Identification of microstructures and their isotopic signatures using microsensor

Several small colonies of Acropora verweyi (Archaeocoeniina) were cultured following the procedure described by Reynaud-Vaganay et al. [38] under constant and controlled conditions, in Centre Scientifc of Monaco (CSM) (Figure 5). Such colonies grew glued onto glass slides (Figure 5). Morphology of the microstructures, using on a scanning electron microscope (SEM Philips 505) was similar to observations performed by Cuif and Dauphin [19] (Figure 3a–i).
The new skeleton, formed under unique controlled condition, was grown on the glass slide, and sampled for the calibration of the growth units (Figure 3j). COC- and fibre-enriched zones were identified using SEM [29]. To characterise separately the isotopic signature of fibres and COC, analyses were focused on the microstructures earlier identified on the newly formed skeleton on two zones (Figure 3a–c; Figure 3j). We then focused our measurements around the theca of the newly formed skeleton (Figure 3k) where Gladfelter [39] recognised large amounts of “fusiform crystals” (Figure 3e). The sampling of the septae aimed
at confirming the presence of both COC and fibres as they have been identified from SEM observations [26].

The present study, confirmed that there was a strong relationship between isotopic value, crystal shape and skeleton morphology [29]. Crystals called “fusiform” by Gladenker [39], according to their shape, show the same isotopic values as COC. We distinguished in septa both COC and fibres (Figure 3k). This confirmed microscopic observations of septa [21] showing discontinuous COC surrounded by fibres.

Isotopic fractionation was likely of kinetic origin, the rate changing according to microstructure. Skeleton microstructures \( \delta^{18}O \) shed in light how chemical and/or physical processes might be adapted by biology to form crystals characterised by specific shapes and distributed following a hierarchical arrangement. The present study demonstrated that the presence of organic molecules (the organic matrix located at the interface tissue-mineral (Figure 1) had the capability to control the mineral deposition mechanism. Probably, the influence of external factors should be superimposed on the chemical signature of coral biomineral genetically determined).

3.3 Monthly calibrations on coral Porites

The preliminary step of climatic reconstruction using Porites skeleton, the genus more often analysed in this context, consisted of the assessment of seasonal \( \delta^{18}O \)-seasonal temperature calibration based on monthly instrumental temperatures over the last decades covered by the core. Sampling was conducted along the coral’s growth through time, following the maximal growth rate perpendicular to the annual density bands shown by X-ray [40].

At millimetre size scale, it was also possible to highlight the strongly significant linear relationship between the constants of seasonal \( \delta^{18}O \)-seasonal temperature calibrations and to relate behaviour of the constants of the seasonal-\( \delta^{18}O \)- and Sr/Ca-seasonal temperature calibrations to the presence of two crystallographic units. Following DeLong et al. [40], fibres insuring the thickening of a colony should be preferentially deposited during a less active photosynthesis, whereas COC insuring axial growth should be formed during high photosynthetic activity. Juillet-Leclerc and Reynaud agreed, however, they demonstrated that growth mode was not so simple [34].

In order to test seasonal \( \delta^{18}O \)-seasonal temperature calibration variability including the seasonal light effect, calculated for several coral cores collected on a given site, at different temperature ranges, we considered studies conducted on several Porites colonies from three sites. The mean annual temperature offshore Amédée Island, New Caledonia (22°29’ S, 166°28’ E) was 24.72°C, over the period 1968–1992 [41, 42], while at Clipperton Atoll (10°18’ N, 109°13’ W) the mean annual temperature was 28.5°C, over the period 1985–1995 [43] and in the Flores Sea, Indonesia (6°32’ S, 121°13’ E) the mean annual temperature was above 28°C, over the period 1979–1985 [44].

We assumed that calibrations measured on different coral colonies grown at a given site (New Caledonia, Clipperton or Indonesia) differed according to various light sensitivities due to depth or light incidence or acclimation because seasonality strongly affected light variations, and was likely different following site location (Figure 6a). However, calibration constants calculated from monthly data for Porites remained strongly correlated (Figure 6b) as we previously observed for annual \( \delta^{18}O \)-annual temperature calibrations.

As seasonal \( \delta^{18}O \)-seasonal temperature calibrations presented similar behaviours, even in different sites characterised by distinct \( \delta^{18}O \) seawater, they did not reflect classical thermodynamics.
Could Coral Skeleton Oxygen Isotopic Fractionation be Controlled by Biology?

Seasonal $\delta^{18}$O of Porites [41-44]

Figure 6.
Porites monthly $\delta^{18}$O from [41–44] (a and b). Monthly $\delta^{18}$O-monthly temperature calibrations for coral Porites and annual $\delta^{18}$O-annual temperature for Porites group as defined in Figure 4c (a) and associated constant relationship (b).

4. Coral cultures simulating different environmental conditions

4.1 Test of temperature

New technique of culture was developed to calculate $\delta^{18}$O-temperature calibration for Acropora sp. The experiment was conducted in Centre Scientific of Monaco (CSM) using colonies of the branching zooxanthellate scleractinian coral, Acropora sp. (Figure 5a and b), in the Gulf of Aqaba (1 m depth) [38]. The nubbins (new colony fragments) were collected from unique parent colony. The specimens were glued on glass slides. Chemical conditions were kept constant during the experiment, as $\delta^{18}$O$_{\text{seawater}}$ (1.29 ± 0.01‰ vs. SMOW) measured in the aquaria under light (260 µmol m$^{-2}$ s$^{-1}$) on a 12:12 h photoperiod [38]. Five temperatures were tested on six coral fragments. The skeletal powder was treated following the method described by Boiseau and Juillet-Leclerc [45].

The calibration given by the experiment (Figure 5c) might be expressed as:

$$\delta^{18}O_{\text{coral}} = -0.27 \times \text{SST} (°C) + 3.22 \quad (8)$$

with N = 5 and $R^2 = 0.96$.

As $\delta^{18}$O$_{\text{seawater}}$ = 1.29 vs. SMOW = 1.02 vs. PDB was constant, the calibration might be expressed as:

$$\delta^{18}O_{\text{coral}} = -0.27 \times \text{SST} (°C) + 5.41 \quad (9)$$

4.2 Test of light intensity

Heterotrophy and photosynthesis were linked and were difficult to separate in field experiments. Coral cultures enabled the investigation of each parameter at a time [34, 46].

Tips from 24 branches were sampled from a single parent colony of Acropora sp. All colonies were cultured for 6 weeks under a light intensity of 130 µmol m$^{-2}$ s$^{-1}$. The ring skeleton deposited on the glass slide was then removed with a scalpel [38] dried overnight at room temperature and stored in glass containers pending isotopic analyses. Thereafter, colonies were cultured for an additional period of 6 weeks under a light intensity of 260 µmol m$^{-2}$ s$^{-1}$, and their isotopic composition...
was determined (Figure 5d). The extension of new aragonite on the glass slide was assimilated to linear extension.

In the first time [46], the averaged results showed that daily calcification, net photosynthesis significantly increased with increasing light and skeletal δ18O_coral were more negative under low light than high light, −4.2 versus −3.8.

Another interpretation, considering each colony was later published [34]. Following the evolution, δ13C_coral increasing or decreasing, two populations appeared: one responding to light with increasing net photosynthesis associated to low linear extension and the other characterised by poor net photosynthesis associated to high linear extension (Figure 5d).

We suggested that different behaviours were due to different zooxanthellae amounts contained by colonies.

4.3 Factorial design of three temperatures and two light intensities

Conditions applied to each tank were referred in the following as (light in μmol photons m−2 s−1, temperature in °C): (200, 22), (200, 25), (200, 28), (400, 22), (400, 25) and (400, 28) [15, 48].

Culture procedures are similar to what was described in Figure 5a and b. Responses of photosynthesis and zooxanthellae density are displayed in Figure 2.

Calibrations calculated from the mean δ18O values for each temperature regime were consistent with those previously published (Figure 2c) [49, 50]. δ18O versus temperature calibrations of nubbins cultured under LL and HL were both highly significant (R² = 0.94, N = 18, P = 0.001 and R = 0.96, N = 18, P = 0.001, respectively). The slope value was in good agreement with Eq. (2) commonly used for Porites corals with b = −0.20‰/°C [37, 51, 52]. However, the values obtained at 22, 25 and 28°C showed a large scattering both at LL and HL, from 0.5 to 1.25‰ or the equivalent of 2 to 5°C.

By comparing our results with other culture experiments [51–53], differences appeared between various δ18O-temperature (°C) calibrations both regarding the slopes and the intercepts with the temperature scale. We suggested that this could be due to inter-species or inter-colony δ18O differences. Even two calibrations obtained on cultured Acropora exhibited differences (the present study and that of Reynaud et al.) [52].

Mean δ18O values calculated for each temperature did not vary with light, which contradicted observations made of mean physiological parameters, in contrast with other proxies (δ13C, Sr/Ca and Mg/Ca). By changing the light intensity from low to moderate, Juillet-Leclerc and Reynaud [47] recorded a δ18O increase associated with skeletal infilling following a kinetic process. The present experiment, conducted under high light intensities, did not show a similar behaviour. We suggested that temperature and light effects on isotopic composition were competing. The results of the present experiment indicated that, under the chosen conditions, the temperature effect was more important than the light effect. This was illustrated by the weak discrepancy in the mean δ18O recorded at 28°C.

Previous culture experiments have been conducted to test the temperature effect on δ18O [38, 51–54]. Due to the sensitivity of the photosynthesis to temperature, δ18O-temperature calibrations will always include temperature-dependent photosynthetic changes, enabling the vital effect due to temperature only to be deconvolved from the total signature. Therefore, all calibrations, even established on a single coral head or from cultured nubbins, are impacted by photosynthetic activity linked to zooxanthellae density. The universal calibration does not exist.
5. A new paradigm for $\delta^{18}$O in coral skeleton oxygen isotope fractionation response to biological kinetic effects

During the last experiment, we failed understanding the light effect on $\delta^{18}$O. We kept one colony cultured in each of six light and temperature conditions previously discussed. Knowing that standard error obtained in the first step of the experiment for six samples cultured in the same condition was between 0.02 and 0.12, we consider that values measured on one colony by using SIMS were representative for each environmental condition [48].

We discussed our results after listing all biological and biological advances, such as (i) conclusions derived from inorganic CaCO$_3$ precipitation disturbed by biology, biased by non-realistic models [8, 55, 56]; (ii) the potential role of the calicoblastic layer composed of proteins, sugars and water [57, 58] and (iii) the role of carbonic anhydrase (CA), ubiquitous enzymes known to act as catalysts for the interconversion of CO$_2$ and HCO$_3^-$ [59, 60].

5.1 Material

The random SIMS measurements were made exclusively on the newly formed skeleton coenosteum (the skeleton portion separating corallites), avoiding newly formed corallites and spines [21]. Samples were distributed along the growth axis from the initial branch to the rim of the expanded tissue (Figure 7a).

Measurements were performed using the Cameca IMS 1280-HR ion microprobe at the CRPG, and the comparison of SIMS and conventional mass spectrometer measurements were made using data from [29, 48].

The $\delta^{18}$O SIMS measurements are displayed as histograms, with bin width of histograms, 0.25‰, depending on the precision of the measurements between 0.09 and 0.32‰ (1σ) (Figure 7b).

5.2 Isotopic results

At 22°C, although the mean values were identical within the analytical error, light had a significant effect on the $\delta^{18}$O distribution. Under LL, the single high bar was surrounded by values spread over 2‰ (Figure 7b). By contrast, under HL, values spread over 4‰, $\delta^{18}$O distribution was bimodal, two high bars were observed, one bar centred on −0.01‰, followed by decreasing values that exceeded the expected $\delta^{18}$O values for aragonite precipitated in oxygen isotope equilibrium in water.

At 25°C, the bimodal $\delta^{18}$O distribution in the two samples exhibited two high bars, with the more depleted in $^{18}$O peak being the same in the two light conditions (Figure 7b).

At 28°C, $\delta^{18}$O distribution was bimodal, the isotopic amplitude being slightly higher under LL than under HL (Figure 7b).

Assuming that two high bars observed in histograms were significant, we used Ashman's D test [61] to strengthen the bimodality of the LL-25°C, LL-28°C, HL-25°C and HL-28°C.

5.3 Discussion

The histograms showed bimodal distributions (except for the colony grown in LL-22°C) caused by distinct kinetic processes. All the colonies were submitted to the diurnal cycle of 12 h light and 12 h dark necessary to grow healthy coral. Therefore, we assumed that, for the high isotopic bar corresponding to the values more depleted in $^{18}$O (Figure 2g), corresponding to the highest kinetic
fractionation, only depending on temperature is associated with nighttime. By contrast, for the other high isotopic bar corresponding to the values less depleted in $^{18}$O, in turn to the weakest kinetic process, depending both on temperature and light could be associated with daytime calcification (Figure 7b and c).

By culturing *Stylophora pistillata* in controlled conditions similar to those in our experiment [62] with a diurnal cycle of 12 h light and 12 h dark, the authors measured calcification and observed that the calcification rate differed according to night and day conditions (Figure 7b and c). The regressions showed that the light calcification rate was about 2.4 times higher than the dark calcification rate (Figure 7c). However, when conditions shifted from light to dark or from dark to light, the calcification...
rate experienced a lag of 25 min between the dark or light regression relative to time (Figure 7c). The lag was likely due to the change of calcification process, which differed between nighttime and daytime. These biological evidences were in good agreement with our biochemical ones (Figure 7b and c). Two assumptions are proposed to explain such a mechanism: a pH change in the extracellular calcifying medium (ECM) and a modification of the biochemical compounds of the organic matrix [62].

Therefore, assuming that the dual high $\delta^{18}$O bars exhibited in the histograms (Figure 7b) were related to the Ca$^{2+}$-pump activity, this could modify the internal pH [62, 63]. If the pH is lower in the dark than in the light [62, 63], in line with McCrea’s [65] calculations, illustrated by Adkins et al. [52], high $\delta^{18}$O bars less depleted in $^{18}$O should be associated with nighttime calcification, and high $\delta^{18}$O bars more depleted in $^{18}$O should correspond to daytime conditions (Figure 7b and c).

However, our experiment demonstrated an opposite distribution: High $\delta^{18}$O bars less depleted in $^{18}$O were identified as daytime skeleton deposits, and those more depleted in $^{18}$O were identified as nighttime deposits. Therefore, we concluded that the two distinct high $\delta^{18}$O bars could not be caused by internal pH diurnal variations. In contrary to the common assumption [9], we demonstrated that mineralisation is not controlled by classical thermodynamic rules, that is, pH, but rather should obey biological kinetic effects, following a mechanism that remains to be identified.

Now we need to identify a mechanism that allowed daytime and nighttime mineralisation to be distinguished, knowing that the second assumption given by Moya et al. [62], a modification of the biochemical compounds of the organic matrix, remained to be examined.

### 5.4 Influence of organic matter on crystallisation

It was supposed that the photosynthetic supply of precursors might modify the biochemical composition of an organic matrix [62], which necessitated an internal rearrangement related to the secretion of specific proteins defending the observed lag. The formation of the organic matrix, controlled by the calicoblastic cells, appeared to be a prerequisite for crystallisation [58–67]. Recently, 36 proteins were extracted from the skeletal organic matrix (SOM) embedded within aragonite crystals, constituting a bio mineralisation toolkit including at least two Carbonate Anhydrase [68] accelerating mineralisation. From this toolkit, four unique proteins, coral acid-rich proteins (CARP), catalysed the precipitation of CaCO$_3$ in vitro [68]. Moreover, some proteins appeared to be differentially expressed between day and night [68, 69]. Therefore, the two different proteins caused different kinetic fractionation processes, inducing during the night higher kinetic isotope fractionation than during the day. We note that calcification rate and isotope fractionation kinetics were drastically different concepts.

Results derived from our last geochemical experiment should drove to responses also addressed by biological study. The fact that classical geochemistry rule, such as pH, could not explain isotopic behaviour led to look for another assumption. Therefore, it highlighted that coral mineralisation could be controlled by proteins secreted by organic matrix. This evidence is now well admitted, supported by multiple biological studies [68, 69].

### 6. Simple models

#### 6.1 Model according to microstructure distribution

As early as 1982, Gladfelter [39] assumed that linear extension and infilling were two independent growth rates, an assumption supported by Juillet-Leclerc and
Reynaud [47]. The authors demonstrated that each growth rate was related to preferential deposition of microstructures, COCs ensuring linear extension and fibres, infilling.

Furthermore, geochemical investigations revealed that crystal isotopic signatures differed [27–29, 48]. COC formation should be related to temperature [39] and fibre deposit depends on both temperature and light [48]. Therefore, temperature and light changes interplayed to determine skeletal isotopic composition.

Sampling conducted as it was described by DeLong et al. [40] included both COCs and fibres. Changes of relative amounts of microstructure as illustrated by X-rays and their respective δ¹⁸O were determined by their mechanisms of formation, unknown so far [29]. Following isotopic laws, the combination of calcification processes and isotopic fractionation could be expressed as:

$$\text{measured } \delta^{18}O = \left[ (x_{\text{COC}} \times \delta^{18}O_{\text{COC}}) + (x_{\text{fibre}} \times \delta^{18}O_{\text{fibre}}) \right] / (x_{\text{COC}} + x_{\text{fibre}}) \tag{10}$$

where $x_{\text{COC}}$ and $x_{\text{fibre}}$ are the relative amounts of the crystal microstructures, with $x_{\text{COC}} + x_{\text{fibre}} = 1$, and $\delta^{18}O_{\text{COC}}$ and $\delta^{18}O_{\text{fibre}}$ are their isotopic signatures depending on temperature and temperature and light, respectively. This expression is likely to be simplistic but closer to the truth than the thermodynamic formula.

Temperature is the prominent factor because included both in the crystal amounts and the isotopic signatures. SST$_{\text{intersection}}$, the corresponding δ¹⁸O$_{\text{intersection}}$ should be related to morphology [22]. When using Eq. (10), the intersection of calibration should be obtained when $\delta^{18}O_{\text{intersection}} = (0.50 \times \delta^{18}O_{\text{COC}}) + (0.50 \times \delta^{18}O_{\text{fibre}})$ or at SST$_{\text{intersection}}$, $\delta^{18}O_{\text{intersection}} = (\delta^{18}O_{\text{COC}} + \delta^{18}O_{\text{fibre}})/2$. As long as temperature does not reach SST$_{\text{intersection}}$, more fibres are formed in the coral skeleton and when temperature exceeds SST$_{\text{intersection}}$, COC are progressively prevailing.

6.2 Model according to environmental parameters

In Pacific Ocean, local zones may be characterised by seasonal and/or interannual environmental parameter amplitude, as ΔSST. By this way, we are able to identify El Niño-Southern Oscillation (ENSO) occurrence [70], over past time.

ΔSST<2°C, seasonal conditions occurring in Tarawa atoll, in Galapagos or in Fiji [71], δ¹⁸O seasonal variability mimics SSS variability. In Fiji, δ¹⁸O is correlated to seasonal precipitation [72]. In other sites, δ¹⁸O variability may indicate oceanic advection. Such events are directly related to El Niño.

If seasonal δ¹⁸O is recorded over several decades, interannual variability may be isolated. By removing the seasonal cycle and applying a 13-month running mean filter from monthly δ¹⁸O, interannual isotopic variability may be regarded as temperature, the greatest fluctuations revealing El Niño-Southern Oscillation (ENSO) occurrence [70], or the global warming over the twentieth and twenty-first century.

When ΔSST ≥ 5°C, as it is occurring off South Korea coast [72], temperature and δ¹⁸O$_{\text{seawater}}$ are both involved in coral skeleton δ¹⁸O variability. Environmental parameters are difficult to separate. If δ¹⁸O shows strong decrease associated to great SST drops, it may be caused by the occurrence of La Niña (characterised by colder SST than the normal conditions) [70].

When 2°C ≤ ΔSST ≤ 4°C as it is recorded in the central tropical Pacific as in Palmyra [73], δ¹⁸O snapshots focused on crucial past periods demonstrate that a 2- to 7-yr bandpassed record (the lower-frequency of ENSO) [70], the interannual isotopic signal highlights El Niño and La Niña occurrences.

Coral skeletal δ¹⁸O is well-suited tool to shed in light climatic events before and after industrial era, to predict future events in the next decades [70].
7. Conclusion

Coral skeleton $\delta^{18}O$ does not obey to classical thermodynamics but rather reflects aragonite microstructure distribution. We demonstrated that oxygen isotopic fractionation is essentially temperature dependent, due to two temperature effects, one following thermodynamic law, decreasing $\delta^{18}O$ when temperature increases, and second, temperature acting through photosynthetic process, increasing $\delta^{18}O$ when temperature increases. Consequently, when temperature changes, $\delta^{18}O$ is affected in opposite senses, confusing the global isotopic effect.

$\delta^{18}O$ measured at millimetre size scale on coral colonies cultured in controlled conditions under varying temperatures and/or light intensities, allows highlighting biologic and isotopic changes associated to environmental factors, acting as vital effect. Measured at microscopic size, $\delta^{18}O$ reveals mineralisation processes. By using the last method coupled with biologic evidences, the role of proteins and enzymes, secreted by organic matrix at the interface tissue mineral is demonstrated, showing the potential biologic control on meralisation.

Applications of stable and radioactive isotopes are supporting sustainable development goals. They are used to study different ecological, biological, chemical and geological systems and understand their dynamics and interactions. Environmental applications of these isotopes include tracing pollutant migration, assessing and predicting climatic changes and planning for water management. This book highlights recent isotope applications in studying the hydrosphere and lithosphere compartments of the Earth. These applications include the use of natural and anthropogenic isotopes to understand the natural processes in these compartments. Chapters focus on soil distribution and sedimentation, dating tectono-metamorphic events, assessing brine origin, planning for water management and the effect of variation of environmental conditions on the biological and isotopic changes in coral skeletons.
